Declaration

Declaration

I declare that the thesis entitled "Modeling, Simulation and Experimental Investigation of Charge Transport Properties of Dye Sensitized Solar Cells" has been prepared by me under the guidance of Dr. (Prof.) Piyush Kuchhal (Supervisor), Department of Physics and Dr. (Assoc.Prof.) Kanak Pal Singh Parmar (Co-Supervisor), Department of Physics, University of Petroleum and Energy Studies (UPES), Dehradun. No part of this thesis has formed the basis for the award of any degree or fellowship previously.

Abstract

Population growth significantly expanding the boundaries of residential areas and living standard for the mankind on the globe which further increases huge demand of electricity consumption. To meet the tremendous growth in energy consumption, electricity production through renewable energy resources can be considered as a fastest-growing energy sources to meet the demand of rapid growth of electricity generation. The Sun is the source of energy (clean and free) available to mankind which is pervasive, readily available and renewable. Unlike fossil fuels, which are found only in a few areas, solar energy is freely available in every part of the world. Thus, all countries can benefit significantly from solar energy, regardless of their geographical position. So, it is essential to harness the sun's irradiation to produce electricity. Solar cell technology is one of the suitable technologies to harness the solar energy to produce power. Among the various solar cell technologies such as silicon solar cell, dye-sensitized solar cell (DSSC), organic photovoltaic, quantum dot solar cells and perovskite solar cell, DSSC solar cell technology is adopted because of its attractive features such as low cost, high power conversion efficiencies under cloudy and artificial light conditions, offer transparency and optimum performance to cost ratio.

DSSC has a sandwiched like architecture based on key components: working electrode (photosensitive dye adsorbed on nano structured metal oxide semiconductor based electrode), a liquid redox couple and counter electrode which plays important role to achieve optimized photovoltaic (PV) performance. On light irradiation, the charge collection efficiency of DSSC depends on generation-recombination and transportation of charge carriers, dye of suitable energy band gap with a larger optical absorbance, charge transfer process at electrode/dye/electrolyte interface and losses of charge due to kinetics role of working electrode's light absorptivity/energetics of dye and transportation of redox ions.

In order to improve the efficiency of the DSSC, it is required to optimize the charge transport properties of the key components of DSSC. This research work is mainly focused on optimizing the properties (thickness and morphology) of working electrode (WE) of the DSSC in order to achieve the optimized PV performance.

An highly crystalline TiO_2 powder consisting of morphologically rice-like nanoparti-

cles is synthesized by a simple hydrothermal process using a premixture of titanium isopropoxide, ethanol and aqueous ammonia. An efficient mechanism decoupling hydrolysis and condensation promotes the formation of a rice-like morphology. As the average particle size and BET properties of nanorice-like TiO_2 were found to be quite similar to a commercially available TiO_2 (Degussa P25), their photoelectric properties were compared as a DSSC electrode. Under 1 sun irradiation the photovoltaic efficiency of nanorice-like TiO_2 was measured to be ca. 20 % higher in contrast to the mediocre efficiency (~ 5.45 %) of P25. We suggest that together with a generally exploited reference, such nanorice-like TiO_2 could also be adopted as a model material for various applications.

A comparative investigation involving experimental and modelling-simulation is carried out to maximize the photovoltaic conversion efficiency (η) of a DSSC device assembled using N719 dye, an iodide redox liquid electrolyte and TiO_2 electrode. The measured current density-voltage (J-V) characteristics under 1 sun condition of a pre-assembled DSSC is simulated in a tiberCAD based microscopic model (TCMM) along with single-diode based macroscopic model (SDMM). The calibrated model parameters are then utilized for predicting a maximum η of a DSSC belonging to an unknown electrode's thickness (L). The microscopic simulations provided a good qualitative nature of J-V characteristics curves for different L and η values. A complete and best J-V curve fitting is achieved using a TCMM by incorporating an unaccounted series resistance of a FTO substrate. Particularly, model simulated J-V characteristics matches perfectly well to experimental results of a post-assembled DSSC device ($\eta \sim 5.46$; $L \sim 12.0 \mu\text{m}$) with a tolerable error (< 0.1 %).

The theoretically modeled equations defining various bulk and interface impedances are incorporated with EIS spectrum analyzer software to fit the simulated EIS curves with experimentally measured EIS curves to evaluate the charger transfer and recombination properties of the assembled DSSCs. EIS fitting parameters investigated to study the impact of WE thickness on the charge transport properties of assembled DSSC. It is observed that the charger transfer resistance at TiO_2 /electrolyte interface (R_k) and series resistance (R_s) are reduced from $8 \Omega\text{cm}^2 \rightarrow 4.05 \Omega\text{cm}^2$ and $14.5 \Omega\text{cm}^2 \rightarrow 10.06 \Omega\text{cm}^2$ respectively which shows consistency with improvement in electron life time (τ_e) from $5.8 \text{ ms} \rightarrow 12.4 \text{ ms}$ for increasing WE thickness, $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$. The combined impact of significant reduction in R_k and R_s along with improved trend of τ_e can be considered as major factors for efficient electron injection across Dye/ TiO_2 interface hence increases short circuit current (I_{sc}) from $1.485 \text{ mA} \rightarrow 2.365 \text{ mA}$ and photovoltaic conversion efficiency (η) from $3.55 \text{ \%} \rightarrow 5.46 \text{ \%}$ for $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$, respectively. Moreover, a remarkable increment in η (~ 45 %), τ_e (~ 56.3 %) and a noticeable reduction in R_k (~ 38.75 %), R_s (~ 23.8 %) are observed for WE variations ($L = 3 \mu\text{m} \rightarrow 6 \mu\text{m}$).

Acknowledgement

First and foremost, I would like to thank Almighty God for giving me the strength, knowledge, ability and opportunity to undertake this research study and to persevere and complete it satisfactorily. Without his blessings, this achievement would not have been possible.

I would like to express my sincere gratitude to my supervisors Dr. (Prof.) Piyush Kuchhal and Dr. (Assoc.Prof.) Kanak Pal Singh Parmar for their continuous support in my Ph.D related study and research, for their patience, motivation, and immense knowledge. Their guidance helped me in all the time of research and writing of this thesis. I could not have imagined having better advisors and mentors for my Ph.D work.

I would like to express my heartfelt gratitude towards the Hon'ble Chancellor, Hon'ble Vice Chancellor of UPES and Dr. (Prof.) Kamal Bansal, Snr. Director Academic Development (UPES) who gave their kind consent to carry on this work and for providing support throughout this work.

I am thankful to Dr. Gurvinder Singh Virk, Dean SOE for providing consistent motivation to put best effort in this work.

I am also thankful to Dr. Sushabhan Choudhury (HoD, EEE), Dr. R. Gowri, Dr. Ranjan Mishra, Dr. Gagan Anand and entire faculty members of Electrical and Electronics Eng. Department for providing support and motivation in my research work.

I am also thankful Dr. D K Avasthi (Dean, R&D) and entire team of Research and Development Department for supporting my research by a SEED grant from UPES (UPES/RnD/122018/06). I am also thankful to the staff members of Nano science Lab and Pharmacy Lab(UPES).

I would be failing in my duties if I miss to thank Mr. Raj Gaurav Mishra and Dr. Syed Mohammad Tauseef for their constant help and support. I am also thankful to all of my friends who lent constant motivation and support.

The greatest sense of acknowledgement would go to my family members: my parents, my sisters and to my wife who have been in the roots of whatever I am and have achieved in my life including this research work.

Pt	Platinum	ω_{CE}	Characteristic frequency of electrolyte/CE interface
e_{cb}	Electron in conduction band	ω_D	Characteristic frequency of electrolytes diffusion
ϕ_{ph}	Intensity of the incident light	R_{Pt}	Charge transfer resistance at electrolyte/CE interface
Φ_{coll}	Collection efficiency	Z_{Pt}	R-C equivalent impedance at electrolyte/CE interface
Φ_{reg}	Generation efficiency	C_{TCO}	DLC at exposed TCO/electrolyte
Φ_{inj}	Injection efficiency	C_{Pt}	Equivalent capacitance
I_o	Intensity at front sample	Z_d	Diffusion impedance of I_3^- in electrolyte represented by Warburg element

I	Intensity at back side of sample	R_{CO}	Resistance at TCO/TiO ₂ contact
k_{reg}	Rate constant for regeneration	C_{CO}	Capacitance at TCO/TiO ₂ contact
k_{rec}	Rate constant for recombination	R_{STCO}	Sheet resistance of FTO glass.
ε	Permittivity	R_{OS}	Ohmic series resistance in DSSCs
$\tau_{1/2(inert)}$	Half time without redox mediator	Z_{OS}	Ohmic series impedance
$\tau_{1/2(redox)}$	Half time with redox mediator	C_{Pt}	Equivalent capacitance
η_{reg}	Efficiency of the dye regeneration	R_k	Electron transfer resistance related to e/I ₃ ⁻ recombination
$^{\circ}C$	Degree Celsius	R_d	Electron transport or diffusion resistance,
V_{OC}	Open circuit voltage	n_k	CPE index
J_{SC}	Short circuit current density	Z_{DI}	Diffusion impedance experienced by I ₃ ⁻
η	Efficiency	R_{DI}	Diffusion resistance experienced by I ₃ ⁻
V_{OPT}	Optimum Voltage	D_I	Diffusion coefficient of I ₃ ⁻
J_{OPT}	Optimum current density	δ	Diffusion length of I ₃ ⁻
V_F	Voltage Equivalent to E_F	ω_{max}	Peak frequency)
E_F	Fermi energy level	Z_{WE}	Equivalent impedances for diffusion and recombination process
E_{red}	Redox energy level	Z_{DSSC}	Net impedance across the anode and cathode of the DSSC
V_{red}	Voltage Equivalent to E_{red}	Y_{CPE}	Admittance of CPE
ϕ_{ph}	Intensity of the incident light	n	Ideality factor
eV	Electron volt	$Z_{Uelement}$	User defined element
J_L	Photo current density	W_{sr}	Warburg coefficient.
R_s	Series resistance	W_{sc}	Warburg coefficients.
R_{sh}	Shunt resistance	$Z_{W_{s1}}$	Warburg short terminus

Δ	Gradient	f_k	Peak frequency
$\mu_{I_3^-}$	Mobility of triiodide	τ_e	Electron life time
$n_{I_3^-}$	Concentration of I_3^-	L_n	Diffusion length of electrons
$\phi_{I_3^-}$	Electrochemical potential of I_3^-	L	Electrode thickness
$n_{I_3^-}^-$	Concentration of I_3^- in dark conditions	F	Faraday constant
μ_c	Mobility of cation	R	Ideal gas constant
n_c	Concentration of cations	Å	Angstrom
ϕ_c	Electrochemical potential of cations	S_{BET}	Specific BET surface area
μ_e	Mobility of electrons	V_P	Pore-volume
n_e	Concentration of electrons	D_P	Pore-volume
ϕ_e	Electrochemical potential of electrons	f_p	peaks of characteristic frequency
\bar{n}_c	Concentration of cations in dark conditions	C_μ	Chemical capacitance
μ_{I^-}	Mobility of I^-	k_3	Dye regeneration rate constant
n_{I^-}	Concentration of I^-	$j_{cathode}^0$	Exchange current density
ϕ_{I^-}	Electrochemical potential of I^-	E_{redox}^0	Standard redox potential
$n_{I^-}^-$	Concentration of I^- in dark conditions	J_0	Saturated dark current density
μ	Mobility	W(Q)	Lambert W-function
D	Diffusion Constant	V_T	Thermal equivalent voltage
N_{CB}	Effective density of states	P	Porosity
$G(x)$	Generation rate (e-h pairs)	A	Cell Area
$\alpha(\lambda)$	Absorption coefficient of the dye	$Z(\omega)$	Impedance
$\psi(\lambda)$	Spectral power flux	ω	Angular frequency
R	Recombination rate	$Z(0)$	Impedance at 0 frequency
β	Exponent for the electron density	N_D^+	Oxidized dye molecules concentration

Chapter 1

Introduction

1.1 Global Demand of energy

One of the most important and biggest problems mankind facing today is the incredible increase in energy use. The United States Energy Information Administration (EIA) reported that world's energy consumption will increase by nearly 50 % between 2018 and 2050 as clearly seen from Figure 1.1 The large fraction of increase in energy consumption comes from those countries which are not listed in Organization for Economic Cooperation and Development (OECD), and this growth is focused in regions where demand is driven by the strong economic growth, particularly in Asia [1].

Figure 1.1: Global primary energy consumption by region (2010-2050) [1]

World industrial sector energy (WISE) usage will get increased by more than 30 % between 2018 and 2050 due to the increment in of good's consumption as clearly

seen from Figure 1.2. The industrial sector comprises of manufacturing, agriculture, construction, refining and mining, bags largest share of energy consumption throughout the projection period (2010-50). It is clearly projected that consumption for WISE is predicted to get reached to 315 quadrillion British thermal units (Btu) by 2050.

Increase of nearly 40 % in transportation energy consumption (TEC) can be projected from the reports for 2018-2050. This significant increase in TEC is largely driven by non-OECD countries, where TEC will increase by nearly by 80 % between 2018 and 2050. The growth in personal travel and freight movement can be considered as two major factors responsible for significant energy consumption in these countries as compared to OECD countries. Reports also suggested that energy consumption for residential and commercial of the sector will increase by 65 % in the projected period, i.e. from 91 quadrillion to 139 quadrillion Btu. Moreover factors like urbanization, rising income, and efficiently access to electricity will also lead to rising demand for energy [1] .

Figure 1.2: Global energy consumption by sector (2010-2050) [1]

To meet the tremendous growth in energy consumption, it is also projected that 79 % of increment in electricity generation is projected for 2018-2050 as mention in Figure 1.3. Population growth over the projection period will significantly expand the boundaries of residential areas and living standard for the mankind belongs to non-OECD countries. Hence give rise to huge demand for electrical appliances which further lead to raise the electricity consumption. The development electric vehicles

and rail expansion entering in the fleet of transportation sector is one of the major factor which increases the demand of electricity in the projection period.

Figure 1.3: Global net electricity generation and usage by sector [1]

Figure 1.4: Global primary energy consumption by energy source (2010-2050) [1]

Electricity production through renewable including solar, wind, and hydroelectric power can be considered as a fastest-growing energy sources to meet the demand of rapid growth of electricity generation. Renewable energy resources will be surpassing the petroleum and other liquids to become the most used energy source in projected period (2018-50) as clearly depicted from Figure 1.4. The Worldwide annual energy consumption will get increased by 3.1 %, 0.6 %, 0.4 % and 1.1 % in renewable, petroleum and other liquids, coal and gas consumption respectively between 2018 and 2050. This trend clearly indicates that human being will more rely on renewable energy resources to full fill the energy needs. The increase of more

than 40 % is projected for consumption of global natural gas and net consumption will get reached nearly to 200 quadrillion Btu by 2050. Along with manufacturing of chemical and primary metals, oil and natural gas extraction also account for growing industrial demand. Moreover the demand of global liquid fuels consumption may get increased by more than 20 %, and total consumption reaches more than 240 quadrillion Btu in 2050 (Figure 1.4) [1].

The rapid use of non renewable energy resources (fossil fuels) such as petroleum, coal and natural gas has radically increased in 21st century as compared to the rate of formation of fossil fuels which leads to complete consumption of the fossil fuel reservoir. Hence, providing sustainable energy to mankind will be one of the major challenges. According to the Kyoto Protocol CO_2 emission has to be reduced and this should be done by utilizing less fossil fuel. Hence, the CO_2 problem is another reason why new and environment friendly renewable energy resources are required to be taken into account.

Our capability to meet the future needs of energy lies in the utilization of renewable sources. Among the several kinds of renewable energy sources like solar energy, wind power, hydroelectricity, bio-mass energy, geo-thermal power, and wave/tidal power solar energy can be considered as one of the most promising energy source as the sun irradiates 165 thousand terawatt (TW) of power each day to the surface of the earth. It would be enough to match our global energy requirement by harnessing the freely available energy direct from the sun.

1.2 Solar Energy : Source of Renewable Energy

Solar power is an energy directly received from the sun that can be converted into thermal or electrical energy as per various requirement and applications. Solar energy is the environmentally friendly and freely available most abundant renewable energy source existing for the mankind.

1.2.1 Solar spectrum

The Sun is a source of black body (BD) radiation emitting everlasting amount of energy at 5500 degree K with very wide spectrum, stretching out from the X-rays

wavelength (0.01 nm – 10 nm) to Radio wavelength (> 1 mm) with the spectral irradiance peak at 525 nm. Along with protecting the earth surface from excessive high energy radiation [2], the Earth’s atmosphere also transform the profile of the solar spectrum as shown in Figure 1.5 .

Figure 1.5: Solar irradiance spectrum reaching at the earth’s atmosphere [2]

The earth’s atmosphere provides attenuation to the solar spectrum which depends on the atmospheric thickness (path length; PL) covered by the sun rays reaching the earth’s surface. The air mass coefficient (AM) defines the direct optical path length through the Earth’s atmosphere, expressed as a ratio relative to the path length covered vertically upwards, i.e. at the zenith. The AM is used to characterize the solar spectrum reaching at the earth’s surface after absorbing the solar radiation by the atmosphere. For a path length L through the atmosphere, and solar radiation incident at zenith angle z relative to the normal to the Earth’s surface (Figure 1.5), the air mass coefficient (AM) is given by eqn.1.1, where L_0 is the path length at zenith (perpendicular to the Earth’s surface) at sea level.

Figure 1.6: Solar radiation incident at angle z relative to the normal to the Earth's surface representing the air mass coefficient (AM)

$$AM = L/L_0 \approx \frac{1}{\cos z} \quad (1.1)$$

AM0, meaning 'zero atmospheres,' is the spectrum outside the atmosphere, and AM1 means that the sun is radiating directly perpendicular to the earth's surface ($z = 0^\circ$, relative atmospheric thickness = 1; (L/L_0)), where AM1.5 means relative atmospheric thickness (L/L_0) is 1.5 appears at $z = 48.2^\circ$. Most of the earth's population is living at the latitudes where the sun radiates its energy is located at the angle is close to $z = 48.2^\circ$ throughout the year. Therefore overall annually standard solar irradiation reaching at the earth's surface can be represented by parameter AM1.5 which further can be opted as a standard potential parameter for photovoltaic (PV) measurements of solar cells [3].

1.2.2 Harnessing of Solar Energy

Solar technologies can harness solar energy for a variety of uses, including power generation, lighting or comfortable indoor environments, and domestic, commercial or industrial water heating. A simple and elegant way to harness the energy of

the sun is photovoltaic (PV) technology. PV devices (solar cells) are unique in that they convert the incident solar radiation directly into electricity, making them robust, reliable and long-lasting without noise, pollution or moving parts. Solar cells have found in various application such satellites and space missions, solar car, solar water irrigation and solar power supply etc. This has led to a strong research interest for discovering new ways to use cheaper and more efficient techniques for solar energy.

1.3 Types of solar cell technology

In Photovoltaic (PV), photo means light and volt means to measure the electricity. In 1839, Becquerel reports the PV effect by observing a system where a current was flowing across two metal electrodes (Ag) immersed in an electrolyte solution upon light irradiation [4]. Based on the parameters; property of photosensitive material, components of PV system, optimum photo conversion efficiency available, and cost of PV power generating system, Martin Green has classified PV solar cells and their technology into three major categories described below.

1.3.1 First Generation of PV systems: 1970s

Silicon is one of the most abundant elements on earth (20 % of the earth's crust) and found in the form of silica sand (SiO_2). The abundant nature of silicon makes it an attractive material for semiconductor industry. These PV cells are used manufacture from crystalline silicon (c-Si) based semiconductor material suitable for PV applications, with energy band gap of 1.1 eV. Crystalline silicon solar cells are further classified into two main types on the basis of silicon wafers manufacturing process [5] shown in Table 1.1.

Table 1.1: Classification and performance of 1st generation solar cells

Sr.No	Type of c-Si solar cells	Silicon Wafer purity	Efficiency
1	Monocrystalline solar cells (Mono c-Si)	Highest-grade silicon	20-25 %
2	Polycrystalline (Poly c-Si)	Lower silicon purity	13-16 %

1.3.2 Second Generation of PV systems: 1980s

Conventional technologies employed for manufacturing crystalline silicon for PV application deal with various complex processing steps and required great deal of work. In the 2nd generation, a few micrometers thick of multilayer of semiconductor materials are deposited on low-cost substrates such as glass, flexible plastic or stainless steel while retaining the first generation of PV efficiencies. As a result, in order to absorb the same amount of sunlight, they need less semiconductor material to make due to its better light absorption coefficient. Furthermore, it is possible to pack thin films into compact and lightweight structures. Table 1.2 lists the commercially developed thin film solar cells [6, 7]:

Table 1.2: Classification and performance of 2nd generation solar cells

Sr.No	2 nd Generation solar cells	Efficiency
1	Amorphous silicon (a-Si)	6-7%
2	Cadmium Telluride (Cd-Te)	15.8 %
3	Copper-Indium-Selenide (CIS)	7-16 %
4	Copper-Indium-Gallium-Diselenide (CIGS)	20.3 %

1.3.3 Third Generation of PV Systems: 1990s

Though the theoretical upper limit for converting sunlight to energy is 33% for a conventional solar cell, the Carnot limit is approximately 95% for the same. This opens the possibility to increasing the efficiency of solar cells by two to three times if various strategies for raising efficiency without incurring excessive expenses can be implemented. There is a lot of research going on to develop low-cost semiconductor materials that can have their bandgap regulated for maximum performance, allowing to adjust the absorptive properties of the solar cell. This is what third generation solar cells have attempted for alternative materials to harvest solar energy. In recent years, new solar cell concepts have been introduced to enhance PV performance. Cells of the third generation are less commercially sophisticated 'emerging' techniques. Organic Photovoltaics (OPVs), Copper Zinc tin sulphide (CZTS), Perovskite solar cells, Dye-Sensitized Solar Cells (DSSEs), and Quantum Dot solar cells are all designed to combine the benefits of first and second generation systems. These

technologies are expected to play a significant role in fast-growing PV areas due to low-cost materials and easy manufacturing and classification with the performance measuring parameters are listed in Table 1.3 [8].

Table 1.3: Classification and performance of 3rd generation solar cells

Sr.No	3 rd generation solar cells	Material based	Efficiency	Charge Injection Process	Advantage	Limitations
1	PV technology with concentrators	Silicon-based cells	20%-25%	At the interface of Si semiconductor junctions	Less PV material, hence less cost; Higher productivity throughout the day due to tracking	Lense fitted solar trackers increases architecture's complexity)
		Multi junction solar cells using III-V	40%	At interface of multiple junctions		
2	Dye Sensitized Solar Cells (DSSCs)	Dye adsorb on nano structured semiconductor material	5%-15%	From the excited photosensitive dye	Fabrication from cheap materials and low cost; Higher temperature performance; Low light performance	Very few dyes absorb broad solar spectrum.
3	Organic Solar Cells	Organic polymer materials for electron and transport layers	4%-5 (commercially), 6%-8% (laboratory)	Organic polymer materials	Lightweight and flexible	Low η and instability over time

1.4 Dye Sensitized solar cells (DSSCs)

An interesting development of solar cell technology today is that of new type of photochemical solar cell invented by O'Regan and Grätzel in 1991 which is known as Dye Sensitized Solar Cell (DSSC) [8]. It has attracted a lot of interest in recent years, in research as well as in industry. A DSSC is considered as potential photo electrochemical energy device with additional flexibility characteristics and a lower production cost due to its simple fabrication process [10].

$$S = S^+ + e \quad (1.2)$$

A DSSC consist of a nanoporous working electrode (WE: adsorbed by suitable photosensitive dye molecules), iodide(I^-)/triiodide(I_3^-) based redox electrolyte and a counter platinum (Pt) electrode. The adsorbed dye molecules get excited upon light illumination and injects electron in the conduction band (CB) of a working electrode as given by eqn. 1.2. The injected electron diffuses through electrode (inter-connected network of TiO_2 nanoparticles) until it reaches the back transparent conducting oxide (TCO) or recombines. The excited dye (S^+) on TiO_2 surface is then reduced back to its original state (S) by the redox electrolyte (I^-) shown by eqn. 1.3. This reduction process changes the equilibrium concentrations of redox electrolytes and creates a concentration gradient, which tend to diffuse I_3^- towards Pt electrode to preserve the equilibrium concentration of the redox electrolytes and completes the close circuit shown by eqn. 1.4. Charge transport between the rear Pt/TCO electrode and the dye molecules is accomplished by means of I^-/I_3^- redox electrolyte [10]- [12].

To obtain a higher efficiency (η), the key challenges are thus to enhance specific role of individual components of a DSSC viz. working electrode (WE), photosensitive dye, counter electrode (CE), an electrolyte; the bulk interfaces and various complex processes occurring in a DSSC.

1.5 Motivation for the work

The conventional energy resources (petroleum, coal, natural gas, fossil fuel etc.) are present in limited quantity on the earth and are being used for a long time. Conventional energy resources are used extensively by mankind and its demand of usage is so high that the reserves have got depleted to a great extent. Fossil fuels (coal, petroleum, and gas) containing carbon dioxide (CO_2) and other greenhouse gases (climate change drivers) are primarily part of present and past energy systems. Fossil fuel depletion and its environmental effects contribute to raising global awareness of the immediate need to identify alternative renewable energy options in

order to fulfill the world's requirements to sustain a high quality of life. The main pillar for human well-being, economic growth and poverty alleviation is access to electricity. Ensuring that everyone has enough energy access is a continuing and pressing problem for global growth.

Very much exploitation and research for new power source has been done not only in the areas of nuclear power generation but also in the area of unlimited renewable energy sources such as solar power generation, wind power generation etc. Sustainable renewable energy development is considered to be one of the most critical scientific and technological problems facing humankind in the globe. The renewable energy sources like solar and wind have shown promise as possible cost efficient alternatives to fossil fuels. The Sun is the source of energy available to mankind which is pervasive, readily available and renewable. Unlike fossil fuels, which are found only in a few areas, solar energy is freely available in every part of the world. Thus, all countries can benefit significantly from solar energy, regardless of their geographical position. Compared to wind energy, the most effective and harmless energy source is solar energy.

Photovoltaic (PV) technology is a simple and productive method to harnessing the sun's energy to produce electricity. In addition with the Silicon (Si) based PV technology, one of the emerging solar cells based on natural and synthetic photosensitive dyes called as Dye sensitized solar cells (DSSC) which can be considered as subject of increasing interest in the PV field during the last few decades. Though a DSSC consists of multiple materials, yet it is a highly realized next-generation potential photovoltaic device that has been widely investigated due to its several advantageous competencies features like working even under a dim/low light and an achievable high value of efficiency (η) using a straightforward, cost-effective and eco-friendly manufacturing process.

1.6 Objectives

The key objectives of this thesis work are:

1. To fabricate the electrode and its characterization for physicochemical properties using different experimental techniques (XRD, SEM, BET).

2. To optimize the electrode parameters to achieve better photovoltaic performance for Dye sensitized solar cells (DSSCs).
3. To propose the new explanatory theoretical models or to improve the (incorporation of parameters) known models of DSSCs.
4. Analysis of various charge transport properties by Electro-chemical impedance spectroscopy (EIS).

1.7 Thesis Organization

The completed research work is compiled in the following chapters:

1.7.1 Chapter 2: Literature Review

Almost all the aspects focused on previous work relevant to the research study of Dye sensitized solar cells are put together in this chapter. It also consists of theoretical, realistic, and application-based assumptions as a result of previous studies on DSSCs. In order to compile information on the earlier research carried out in the field of DSSCs, a comprehensive literature survey is conducted along with its complete architecture. In addition to the analysis centered on working electrode scaling, various morphologies of nanoparticles and their structural effect on dye solar cell performance are also presented along with the different methods of synthesis. The complete set of drift and diffusion process coupled with continuity and Nernst equations are also presented and discussed to describe the working principle of the DSSC. The various characterization techniques in order to investigate the material, physiochemical and photovoltaic properties (J-V) of DSSC required for explain the performance is also included.

1.7.2 Chapter 3: Facile one-pot hydrothermal synthesis of nanorice-like TiO_2 for an efficient dye sensitized solar cell (DSSC)

In this chapter a highly crystalline TiO_2 powder consisting of morphologically rice-like nanoparticles is synthesized by a simple hydrothermal process using a premixture

of titanium isopropoxide, ethanol and aqueous ammonia. The PV performance of assembled DSSC is also compared with P25 based DSSC to analyse the charge transfer properties in order to investigate the impact of morphological and crystalline nature of the working electrode (WE).

1.7.3 Chapter 4: Optimizing photovoltaic efficiency of a dye-sensitized solar cell (DSSC) by a combined (modelling-simulation and experimental) study

In this chapter a comparative investigation involving experimental and modelling-simulation is carried out to maximize the photovoltaic conversion efficiency (η) of a DSSC device assembled using N719 dye, an iodide redox liquid electrolyte and TiO_2 electrode. The measured current density-voltage (J-V) characteristics under 1 sun condition of a pre-assembled DSSC is simulated in a tiberCAD based microscopic model (TCMM) along with single-diode based macroscopic model (SDMM). The calibrated model parameters are then utilized for predicting a maximum η of a DSSC belonging to an unknown electrode's thickness (L).

1.7.4 Chapter 5: Analysis of charge transport properties of dye-sensitized solar cell (DSSC) with TiO_2 working electrode by employing electrochemical impedance spectroscopy (EIS)

The theoretically modeled equations defining various bulk and interface impedances are incorporated with EIS spectrum analyzer software to fit the simulated EIS curves with experimentally measured EIS curves to evaluate the charger transfer and recombination properties of the assembled DSSCs (as mentioned in chapter 3). EIS fitting parameters investigated to study the impact of WE thickness on the charge transport properties of assembled DSSC.

1.7.5 Chapter 6: Conclusion and Future Work

Here the outcomes of the research work are summarised and concluded along with its future aspects.

Chapter 2

Literature Review

2.1 Introduction

In 1991, O'Regan and Grätzel invented a new, functional version of TiO_2 (metal oxide) based dye-sensitized solar cells (DSSCs), which were previously unsuitable for real world applications. DSSCs can be scrutinized as potential photo-electrochemical energy device with additional flexibility characteristics and a low production cost due to its simple fabrication process.

2.1.1 Architecture of DSSC

DSSC has a sandwiched like architecture as show in Figure 2.1 includes the following key components which plays important role to achieve optimized photovoltaic (PV) performance.

Figure 2.1: Architecture of Dye solar cell (DSSC)

2.1.1.1 Working electrode (WE)

A layer of nanostructured semiconductor (metal-oxide) material adsorbed with photosensitive dye of suitable energy band gap is deposited at the surface of glass coated on one side with a thin transparent conducting oxide (TCO) layer of fluorine-doped tin dioxide (FTO) or indium doped tin oxide (ITO). In comparison with other tested TCO, such as indium tin oxide (ITO), FTO demonstrated to have the higher work function (i.e. 4.9 eV in contrast with 4.8 eV of ITO); in addition, the best thermal stability, the least toxicity and low cost made FTO the most performing one for transparent conducting layer. The indium scarcity and the consequent increasing price the sensitivity to different environments both acids and basics and the patterning complications make FTO a better choice. Some more carbon-based materials (carbon nanotubes, nanomaterials, graphene) has been tested but values of sheet resistance and transmittance are below the requirement for application in PV (i.e. $R_s = 10 \Omega\text{cm}^{-2}$ and $Tr = 90\%$).

The semiconductor (metal oxide) layer can be deposited by means of a variety of methods including spraying, spin coating, dip coating, screen printing or the simple doctor blade technique followed by sintering process at a temperature of 450 °C.

TiO₂ has all along been the preferred semiconductor in DSSCs by other metal oxides like ZnO, SnO₂ and Nb₂O₅. Apart from traditional pigment applications, nanocrystalline TiO₂ intrinsically possesses multifunctional attributes enabling it to be deployed in environmental photocatalysts (for treating polluted air or wastewater, self-cleaning windows, antimicrobial coatings); and in efficient electrodes for photovoltaic cells, photo-electrochromics and gas sensing devices.

In the natural environment, TiO₂ is mainly present in three crystalline forms: brookite, anatase (used in DSSC) and rutile. TiO₂ bandgap fits better (3.2 eV in anatase form; absorbs only below 388 nm) with the most successful commercial dyes allowing an efficient electron injection; moreover, it permits a higher dye loading due to the high surface area. Lower chemical stability and higher dark current of rutile form made it less efficient than anatase form. The WE is composed of a mesoporous layer of TiO₂ nanoparticles (10-20 nm) on which the dye molecules are anchored. The high surface area of the particular mesoporous semiconductor (metal oxide) film is important for the efficient device performance, as it allows absorption

of the solar radiation by employing only a monolayer of adsorbed photosensitive dye. Usually, the metal oxide film (ex. TiO_2 , ZnO) is deposited by the screen printing technique, a reproducible system, of easy application for large area device and for spreading out in the PV market.

2.1.1.2 Photosensitive Dye

It injects electrons in the semiconductor electrode (WE) upon illumination; the photosensitive dye is regenerated by the redox electrolytes. The adsorbed dyes act as light-harvesting intermediates in DSSCs; they absorb visible and near-infrared solar radiation and inject the resulting excited electrons into the semiconductor conduction band. After light absorption, the separation of the charge is normally initiated at dye/ TiO_2 /electrolyte interface. Generally, the overall performance of DSSCs also depends on photo sensitizers and electron-transfer kinetics across the interfaces. On the basis of accumulated knowledge of dyes used for DSSCs, the photosensitive dye molecule should possess the following characteristics to generate charge carriers and their injection in the CB of WE efficiently:

- Strong binding between dye molecules and TiO_2 nano particles by means of an anchoring group for efficient electron injection.
- Dye should absorb maximum portion of light spectrum and should also possess high molar extinction coefficient (ϵ , $\text{M}^{-1}\text{cm}^{-1}$) for efficient light harvesting with thinner TiO_2 electrodes.
- The lowest unoccupied molecular orbital (LUMO) of the dye should be located near the anchoring group and above the CB edge of the semiconductor electrode (usually TiO_2) to achieve efficient electron injection into the CB of TiO_2 .
- The dye's highest occupied molecular orbital (HOMO) should lie below the redox mediator's energy level to allow the oxidized dye to regenerate.

The above requirements can be fulfilled by controlling photophysical, electrochemical properties of the dyes and the molecular orientation and arrangements of dyes on the TiO_2 surface. Many polypyridine complex of transition metals and several molecules

such as porphyrins, phthalocyanins, vegetable and artificial bio-inspired pigments have been investigated for being sensitizers for DSSC.

2.1.1.3 Redox electrolyte

The function of the redox electrolyte is to regenerate the oxidized dye molecules by transferring the electrons from the counter electrode (CE) to the oxidized dye and completes electric circuit by mediating electrons between WE and CE. There are two kinetic limitations for a successful redox electrolyte, it must reduce the dye cation before the dye cation recombines with an electron in the CB of TiO_2 and it should not allow the oxidized form of redox ions to recombine with an electron in from the CB of TiO_2 . The dual criteria of fast dye regeneration and slow recombination place a very challenging constraint on identifying effective redox systems.

Literature also reports that for efficient DSSCs, I_3^-/I^- based redox couple is a suitable choice of redox electrolytes. In order to avoid problems (like dye desorption, solvent evaporation and sealing degradation) due to the liquid electrolytes several non-traditional electrolytes like ionic liquids, quasi-solid state and solid state electrolytes have been used in DSSC.

2.1.1.4 Counter electrode:(CE)

The role of CE is to catalyzing the reduction process of the oxidized form of redox electrolytes by the back transfer of electrons, arriving from the external circuit, to the redox system. It acts as cathode for the DSSC. The most used material for making the CE is a thin layer of few nanometers of platinum (Pt) that is deposited on the FTO coated glass and acts as a catalyst. In the last years, the research effort was focused on testing carbon materials such as amorphous carbon, CNTs, or graphite, GNPs, or graphene oxide (GO) for another material for CE preparation. Necessary features for an efficient counter electrode are following:

- The charge-transfer resistance at the electrolyte and Pt CE interface must be low.
- The exchange current density must be high in order to have an efficient electrolyte generation

- High specific surface area

2.2 Working principle of DSSC

Figure 2.2: Energy band diagram of DSSC and various generation and recombination kinetics

From the Figure 2.2 it can be depicted that the adsorbed photosensitive dye molecules get excited (path p_1) upon light illumination from its ground state (S) to its excited state (S^*) as given by eqn. (2.1). Charge separation occurs through photoinduced electron injection (path p_2) from (S^*) into the CB of the WE (semiconductor layer of metal oxide, TiO_2), which results in the oxidation of the dye (S^+) as given by eqn. (2.2). The injected electron diffuses through electrode (inter-connected network of TiO_2 nanoparticles) until it reaches the back FTO glass (path p_3) or recombines (path r_2 , r_3). The excited dye (S^+) anchored on TiO_2 surface is then reduced back to its original state (S , through path p_4) by the redox electrolyte (I_3^-/I^-) as shown by eqn. (2.3). This reduction process changes the equilibrium concentrations of redox electrolytes and creates a concentration gradient, which tend to diffuse towards Pt electrode (CE) to preserve the equilibrium concentration of the redox electrolytes and completes the closed circuit shown by eqn. (2.4). Charge transport between the CE and the dye molecules is accomplished by means of iodide/triiodide redox electrolyte.

$$S(dye) + hv = S^* \quad (2.1)$$

$$S^*(dye) = S^+(dye) + e_{cb}(TiO_2) \quad (2.2)$$

$$2S^+(dye) + 3I^- = 2S(dye) + I_3^- \quad (2.3)$$

$$e(Pt) + \frac{1}{2}I_3^-(electrolyte) = \frac{3}{2}I^- \quad (2.4)$$

Excited dye molecule may relax directly to its ground state (S) by the electron from LUMO to HOMO level through recombination path r_1 (Figure. 2.2) as given by eqn.(2.5) and this process may be responsible for the electron loss but the electron injection rate constant (for path p_2) is 1000 times to dye relaxation rate constant (for path r_1) and dye relaxation can be neglected for electron loss mechanism. CB electrons may be captured by oxidized dye-molecules through recombination path r_2 and given by eqn. (2.6). The neutralization of excited dye should ideally occur via the redox species only and since the dye neutralization rate constant is 100 times higher than conduction band electron captured rate so we can also neglect this electron loss process. CB electrons may also be captured by of the electrolyte (see Figure. 2.2) by following recombination path r_3 as given by eqn. (2.7) and can be considered as dominant path of electron capturing.

The loss of the photoinjected electrons from any recombination process leads to degrade the PV performance of the DSSC. In principle for efficient DSSCs, the regeneration of the dye by I^- ions should be much faster than the recombination of electrons.

$$S^+(dye) + e = S(dye) \quad (2.5)$$

$$S^+(dye) + e_{cb}(TiO_2) = 2(dye) \quad (2.6)$$

$$I_3^-(electrolyte) + 2e_{cb}(TiO_2) = 3I^- \quad (2.7)$$

Indeed, understanding the kinetics of charge-transfer processes is fundamental in order to select the right materials for the optimization of the DSSC structure.

2.3 Techniques for Characterization of DSSC

The DSSC can be characterized to investigate the material properties of each key component or as complete set of solar cell:

2.3.1 For complete DSSC

In this characterization technique, the final assembled DSSC is considered as a main sample to analyze its performance.

2.3.1.1 Incident photon-to-current conversion efficiency (IPCE)

IPCE is a calculation of the solar cell's efficiency at various wavelengths to transform the incoming photons to photocurrent. When illuminated by monochromatic light, it is achieved by calculating the solar cell's net photocurrent. The IPCE is computed as the number of electrons generated by irradiation in the external circuit divided by the number of incident photons and is calculated by using the following eqn. (2.8), where J_{SC} (mAcm^{-2}) is the short circuit current density generated by the monochromatic light; λ (nm) and ϕ_{ph} (mWcm^{-2}) are the wavelength and the incident light intensity of the monochromatic light, respectively. IPCE can also be expressed as the product of light-harvesting efficiency (LHE (λ)), the quantum yield of electron injection ($\Phi_{inj(\lambda)}$), the efficiency of regeneration ($\Phi_{reg(\lambda)}$) and the efficiency dye of collecting the injected electron ($\Phi_{coll(\lambda)}$) at the back contact or FTO. The LHE (λ) can be expressed as $LHE(\lambda) = 1 - 10^{-ABS(\lambda)}$, where $ABS(\lambda)$ is absorbance of the dye adsorbed on nanocrystalline TiO_2 as given by eqn. (2.9). The equations (eqn. 2.8-2.9) emphasize the direct relation between the light absorption properties of the dye, the amount of adsorbed dyes on the TiO_2 surface, $\Phi_{inj(\lambda)}$ and the $\Phi_{coll(\lambda)}$ on the IPCE of the DSSCs. The maximum IPCEs for DSSCs are limited to 80-90 % range; they do not reach 100 % experimentally, probably due to the reflection and absorption losses (10-15 %) of the TCO glass.

$$IPCE(\%) = \frac{1240}{\lambda \phi_{ph}} J_{SC} \cdot 100 \quad (2.8)$$

$$IPCE(\lambda) = LHE(\lambda) \Phi_{inj(\lambda)} \Phi_{reg(\lambda)} \Phi_{coll(\lambda)} \quad (2.9)$$

2.3.1.2 Current density voltage characteristics (J-V)

J-V characteristics are monitored under the standard intensity of illumination (AM 1.5 G, 100mWcm^{-2}) by applying an external voltage between the WE and CE by tracing the current for a given points of external voltage. J-V curve can also be measured under dark conditions (zero light intensity) to analyse the recombination process taking place inside the cell.

2.3.1.3 Electro Chemical Impedance spectroscopy (EIS)

EIS is an effective technique for characterizing the electrical properties across the bulk and the interfaces of materials such as for DSSC to analyse the charge transport properties at $\text{TiO}_2/\text{electrolyte}$ interface, $\text{CE}/\text{electrolyte}$ interface etc and inside the bulk of TiO_2 electrode.

2.3.2 Characterization of DSSC components

2.3.2.1 UV-visible spectroscopy

UV-vis spectroscopy is a widely used technique for analyzing dyes and their ability to absorb the photons at different wavelengths. In this technique, a front side of the sample is irradiated with an intensity of UV-Vis (ultraviolet visible) light and the intensity at the back side of the sample (see Figure. 2.3) is measured. Absorbance is defined by eqn. (2.10), where I_o is the intensity of light at the front side of the sample and I is the intensity to the detected at the back side of the sample. Transmission (T) reflects how much light intensity is transmitted by the sample instead of absorbed and defined by eqn. (2.11). Absorbance (A) is related to the concentration of the sample (C), the molar extinction coefficient (ϵ), and the path length of the light travelled (L) which are expressed by Lambert Beers law and given by $A = C\epsilon L$. Moreover the combined Lambert beers law and UV-vis spectroscopy can be used to investigate the dye coverage (molcm^{-2}) on the TiO_2 nanoparticles.

$$A = \log_{10} \frac{I_o}{I} \quad (2.10)$$

$$T = \frac{I_o}{I} = 10^{-A(\lambda)} \quad (2.11)$$

Figure 2.3: Light illumination across the sample to measure the absorbance

2.3.2.2 Fluorescence spectroscopy

As a function of wavelength, fluorescence spectroscopy calculates the emitted photons upon illumination. Photons are absorbed and electrons excited to higher energy levels by illuminating molecules. Molecules emit photons of lower energy than the first absorbed energy when they relax down to the ground state. In DSSC, the difference between the level of the ground state and the excited level of a dye can also be considered as a possible component for the absorption of the solar cell, so the energy gap between the dye's LUMO and HOMO can be determined from the absorption intercept and the dye's fluorescence spectra.

2.3.2.3 X-ray Diffractometry (XRD)

XRD is a rapid analytical technique primarily used for phase identification of a crystalline material and can provide information on unit cell dimensions. This research method is carried out as a function of the outgoing direction by directing an x-ray beam at a sample and calculating the scattered intensity. The scatter, also known as a diffraction pattern, indicates the crystalline structure of the sample once the beam is separated. In order to describe the crystal structure that most likely produced the observed pattern, the Rietveld refinement method is then used. For DSSCs, XRD is employed to investigate the crystallinity (single or multi-crystalline structure) and phase (rutile, anatase and brookite) of the synthesized TiO_2 nanoparticles.

2.3.2.4 Transient absorption spectroscopy (TAS)

TAS is a pump probe technique by using a laser diode (Nd:YAG) with a 10 ns pulse width to analyze and investigate kinetics of DSSCs in order to estimate the dye regeneration rate constant and the time constants for the dye regeneration over any instant of time. Decay characteristics achieved by TAS technique is further used to measure the decay of the absorption of the oxidized dye with and without redox couple to evaluate efficiency of the dye regeneration (η_{reg}), which is given by eqn. (2.12), where k_{reg} and k_{rec} are the rate constants for the regeneration and recombination respectively. The time constants $\tau_{1/2(redox)}$ and $\tau_{1/2(inert)}$ are the half-times with and without redox mediator, giving the regeneration and recombination half-times.

$$\eta_{reg} = \frac{k_{rec}}{k_{rec} + k_{reg}} = 1 - \frac{\tau_{1/2(redox)}}{\tau_{1/2(inert)}} \quad (2.12)$$

2.3.2.5 Scanning electron microscopy (SEM)

SEM is a technique that uses a focused beam of high-energy electrons to generate a variety of signals at the surface of solid specimens. The electron-sample interaction signals reveal sample information, including external morphology (texture), chemical composition, and crystalline structure and orientation of the sample materials. Data is collected over a selected area of the sample surface in most applications, and a 2-dimensional image is generated that shows spatial variations in these properties. For DSSCs, SEM technique is applied to characterize the micro structural surface morphology (shape, size) of TiO₂ nanoparticles coated on FTO glass.

2.3.2.6 Brunauer, Emmett and Teller (BET) Analysis

BET technique is applied to investigate the desired physicochemical properties of the material (synthesized or commercially available). The BET properties can be measured by N₂ adsorption-desorption at 77 K. Specific BET surface area, pore size and pore volume can be determined by N₂ adsorption isotherms using BET and Barrett-joyner-Halenda (BJH) methods. For DSSCs, BET is applied to evaluate the physicochemical properties of the TiO₂ nanocrystalline powder.

2.3.3 Photovoltaic (P-V) parameters of DSSCs

The P-V performance of any DSSC can be explained in terms of the parameters: (i) photocurrent–voltage curve (JV curve), (ii) open-circuit voltage (V_{OC}), (iii) short-circuit current density (J_{SC}), (iv) Fill factor (FF), and (v) overall conversion efficiency (η). These photovoltaic parameters explained below:

2.3.3.1 Photocurrent voltage (J–V) curve

The J–V curves represent, in general, the most important and most direct characterization method for DSSCs and for solar cells. A typical J–V curve is shown in Figure. 2.4. Analysis of the J–V curves includes the determination of the following parameters: V_{OC} , (J_{SC}), fill factor (FF), maximum power point (MPP, (V_{opt}) and (J_{opt})); and overall conversion efficiency (η).

Figure 2.4: J-V characteristics of DSSC listing performance parameters

2.3.3.2 Open circuit photo voltage (V_{OC})

V_{OC} is usually measured when the current flow in the cell is zero (i.e. open circuited condition, see Figure. 2.4) and defined as the difference in electrical potential between two terminals of a cell under illumination. The maximum V_{OC} of a DSSC corresponds to the absolute difference between the Fermi level ($V_F = E_F/q$) of the

CB of TiO_2 and the redox potential ($V_{red} = E_{red}/q$) of the redox system, I_3^-/I^- , where E_F and E_{red} are the fermi levels of TiO_2 and redox electrolyte respectively.

2.3.3.3 Short-circuit photocurrent density (J_{SC})

J_{SC} (mAcm^{-2}) is measured for DSSC under irradiation at an applied potential of zero volt (i.e. short-circuited condition, see fig. 2.4). It is well associated with the interaction of photosensitive dye molecules and TiO_2 nanoparticles result in significant impact on absorption coefficient of dye and electrode injection process from LUMO level of dye to CB of TiO_2 .

2.3.3.4 Maximum Power Point (MPP)

It represents maximum power density generated by the any solar cell. The points corresponding to MPP (mWcm^{-2}) on the PV curve are given by V_{opt} (optimum voltage, V) and J_{opt} (optimum current density, mAcm^{-2}) respectively and computed as $MPP = V_{opt} \cdot J_{opt}$ (see fig. 2.4) The MPP majorly depends on the sharpness (slope) of non linear region of PV curve.

2.3.3.5 Fill factor (FF)

The fill factor (FF) of a solar cell is the ratio of the maximum power output ($MPP = V_{opt} \cdot J_{opt}$) to the product of V_{OC} and J_{SC} . This parameter indicates the deflection of the J-V characteristic from a square like curve as shown in Figure. 2.4 and expressed by eqn. (2.13).

$$FF = \frac{J_{opt} V_{opt}}{J_{SC} V_{OC}} \quad (2.13)$$

2.3.3.6 Photovoltaic efficiency (η)

The overall conversion efficiency of a DSSC is defined as the maximum output electrical power of the DSSC divided by the energy of the incident sunlight (I) on the active surface area of solar cell. This is also called as solar energy to electricity conversion yield. The overall η of the photovoltaic cell is calculated from J_{SC} (mAcm^{-2}), V_{OC} , (V), the FF and the intensity of the incident light (ϕ_{ph} , mWcm^{-2}), using the eqn. 2.14

$$\eta(\%) = \frac{J_{opt}V_{opt}}{\phi_{ph}} = \frac{J_{SC}V_{OC}}{\phi_{ph}}.FF.100 \quad (2.14)$$

The efficiency is a function of J_{SC} , V_{OC} and FF of the DSSC. Consequently, improvement of the overall conversion efficiency is the result of the optimization of these three parameters. However, a gradual increase in the overall conversion efficiency has been recognized in the past decade. In order to achieve higher photovoltaic conversion efficiency, the key components of DSSC's architecture should be design and synthesize in order to achieve favorable photo physical and electrochemical performance.

2.4 Development in Photosensitizers

The role of dye as a photo sensitizer is unique in DSSC as compared to other solar cells. Dye increases the conversion η of the photo electrochemical cells with photo electrode (PE) of wide band gap semiconductors. The PE itself maybe in transparent to visible and infrared (IR) light spectrum; therefore dye is also one of the component which is responsible for driving the efficiency of the cell. The ability to absorb the wide light spectrum enhances the conversion of photons into electricity.

The techniques like molecular engineering of several organic dyes, metal complexes and natural dyes are widely studied and focused in order to enhance the role of dye for light absorption to improve the η of DSSC. The dye for DSSC are categorized and discussed below:

2.4.1 Complex dyes based on Metal-composites

Dyes composed of chromophores of ruthenium (Ru) complexes which are widely used for the DSSC applications as effective sensitizers [13]. Several complexes of Ru dye eg. Ru poly pyridyl complexes are used as a charge transfer sensitizers and have shown the $\eta \sim 11\%$ under AM 1.5 (100 mWcm^{-2}) conditions. The improvement in the η is noticed because of their efficient charge transfer process and better absorption over a wide visible range [14].

The one of the famous Ru-complex photo-sensitizers is known N3 or red dye which

is developed by Grätzel and his group. Two other dyes reported in the literature are N749 (black dye) and N719. These are most effective sensitizers and because the carboxylate groups attracted to the bipyridyl moiety decrease the ligand π^* orbital's energy and further enhances the absorption spectrum (visible to near infra red region) [15]- [19].

A new kind of ruthenium sensitizers, i.e., JK-91 and JK-92 are synthesized on substitution of one of the 2,2'-bipyridyl-4,4'-dicarboxylate groups in the sensitizer N719 into the conjugated bipyridine of the ancillary ligand to reach the η to 6.22 % and 6.75 %, respectively for DSSCs.

Researchers also synthesized a new Ru(II) sensitizer (A597) and describes its optical, photo voltaic and electrochemical characteristics by employing it for DSSC applications and investigated $\eta = 7.25$ % due presence of ligands (bipyridine and thiocyanateco) to anchor the dye molecules at the TiO_2 surface.

DSSCs based on sensitizers containing supplementary bipyridine ligands (contains, carbazole, fluorene, etc.) tethered to a hydrophobic hexyl substituent were fabricated and exhibit an impressive $\eta = 5.94 - 6.91$ % more than ($\eta = 6.36$ %) and are shows comparable performance for dye N719 ($\eta = 7.13$ %) [20]. The impact of ligand structure over photovoltaic performance (PV) of DSSC is also investigated by designing and synthesizing three thiocyanate free cyclometalated Ru-II complexes as sensitizers for absorbing near IR regions and producing η of 5.53 %, 3.81 % and 3.43 %, respectively [21]. Few of the PV parameters of DSSCs based on metal complexes that have been evaluated as photosensitisers are listed in Table 2.1.

Table 2.1: PV parameters of DSSCs based on metal complexes that have been evaluated as photosensitisers

2.4.2 Metal-free organic dyes

Metal-free organic donor–acceptor (D–A) dyes have high extinction coefficients to absorb more irradiation with less dye coating thickness [41]. This makes organic dye suitable for TiO₂ films. More over due to their ecofriendly nature and relatively low cost, research has been grown to synthesize metal free organic novel sensitizers in recent years. Due to phototherapeutic and photochemical application, many organic dyes, such as perylenes, indoline dyes, hemicyanine dyes carbazole dyes triphenylamine dyes, porphyrin dyes, coumarin dyes, and phthalocyanine dyes, have been intensively investigated as sensitizers and some have achieved efficiencies more than 10 % [42]. Employing co sensitization with an organic dye (NKX 2553 or D131) to improve the η of black dye based DSSCs. In addition to this the η was further enhanced up to 11.6 % by employing co adsorbent (deoxycholic acid, DCA) in DSSC [43]. A new metal-free organic dye is also synthesized for DSSCs with η of 5.1 %.

2.4.3 Natural dyes

The promising alternative photosensitizers for DSSCs are natural dyes because it is cheap, versatile, plentiful, and sustainable. Natural dyes exhibit very less consumptions of noble metals which make them important area of study for research. Flowers, leaves and fruits have different colors in nature producing pigments for DSSC application [44]. Many pigments have been investigated as listed in Table 2.2. Pigment molecules and dyes, which are primarily derived from plants (sometimes from animals or minerals) with or without chemical treatment, are natural colourants. If it is possible to manufacture an alternative dye, such as a plant dye, as well as ruthenium complex dyes or organic dyes, it would be of interest for both economic and environmental reasons. A aim of research on plant-based dyes for photo electrochemical solar cells is to produce a dye that can be used with reasonable efficiency for the same purposes as ruthenium dyes. Many natural dyes, including anthocyanins [45], tannins [46], carotenoids, cyanines [47], flavonoids [48] and chlorophylls [14]- [49], have been used as sensitizers in DSSCs.

2.5 Development in electrolytes

The electrolyte is considered as performance driving components in Dye sensitized solar cells (DSSCs). It provides inner charge transport between electrodes and effectively regenerates the dye and itself during operation of DSSC. Moreover it has immense influence on the photo conversion efficiency (η) and stability of the device for long duration. In order to achieve rapid dye regeneration, iodide should be present in sufficient concentration or diffusion of iodide ion should be fast. The non viscous electrolyte solution provides free path for diffusion of electrolyte ions effectively. Hence, required low electrolyte concentration is enough for dye regeneration for non viscous electrolyte solutions. For viscous electrolyte solutions, high concentration of electrolytes hinders the diffusion process results decreases the dye regeneration rate. An optimized viscosity for electrolyte solution is required for proper diffusion of iodide to achieve better dye regeneration rate. Transport of triiodide to the counter electrode is mostly driven by diffusion; can be limited by lower concentration of triiodide or by high viscous solvent causes an over potential results lowering the open circuited voltage (V_{OC}) of the DSSC.

The performance of the DSSC is determined by its Photovoltaic parameters (PV) parameters (J_{SC} , FF, V_{OC} , η) which are significantly affected by the type electrolytes and their interaction with electrodes in DSSCs. For instance PV parameters can be significantly affected by redox couple transport process, diffusion of electrolytes and the charge transfer resistance across electrolyte/electrode interface and redox potential of the electrolyte respectively. Wide research has been carried out on the electrolytes in order to improve the PV performance of the DSSCs [60]. Various electrolytes utilized to develop the DSSCs are further classified on the basis of their compositions, physical states and formation mechanisms named as liquid electrolytes [61]- [62], quasi-solid electrolytes [63]- [64] and solid-state conductors [65].

2.5.1 Liquid electrolytes

In 1991, O'Regan and Gratzel pioneered a successful DSSC using a very rudimentary liquid electrolyte (LE) consisting of an organic solvent and a dissolved I^-/I_3^- redox pair without additives. Liquid electrolytes (LEs) should be chemically and physically stable in DSSCs. Due to the excellent characteristics, such as smooth preparation, better conductivity, superior wetting property at electrode and electrolyte interface and low viscous property (for efficient redox reactions), liquid electrolytes have been continuously preferred for the DSSC applications to produce efficient devices as listed in Table 2.3.

Table 2.3: PV performance of DSSCs based on liquid electrolytes using ionic liquid as solvents

Electrolyte composition	Dye	J_{SC} mAcm ⁻²	V_{OC} (V)	FF	η (%)	$D(I_3^-)$ ($\times 10^{-7}$ cm ² s ⁻¹)	Ref.

2.5.2 Quasi solid state liquid electrolytes (QSSELS)

The DSSC achieves great growth by using LEs as charge transporters. The use of LEs, however, causes some practical problems, such as solvent leakage and volatilization, dye photo degradation and desorption, CE corrosion and cell sealing for long time application. These kinds of drawbacks can be solved by employing QSSELS in DSSCs. Although the efficiencies of DSSCs with QSSELS are often lower than those of DSSCs with LEs, due to improved stability and better sealing efficiency, QSSELS can become viable alternatives to LEs [63], [75], [64]. QSS or semisolid-state is a special state between solid and liquid-state substances. Few of the DSSCs based on QSSELS are listed in Table 2.4

Table 2.4: PV performance of DSSCs based on QSSELS

Electrolyte composition	Dye	J _{SC} mAcm ⁻²	V _{OC} (V)	FF	η (%)	σ mScm ⁻¹	Ref.

Macromolecular or supramolecular nanoaggregate systems characterized by remarkable ionic conductivity, typically higher than 10^{-7} S for DSSCs, usually higher than 10^{-3} S, are termed as QSSEs. Moreover QSSEs have both the solid cohesive property and the liquid diffusive property, namely along with greater long-term stability than LEs. Other than DSSC applications, QSSEs are also employed in other electrochemical and electronic applications, such as fuel cells, actuators and sensors, secondary batteries, fuel cells, electrochromic displays and supercapacitors, and because of their exceptional properties [84]- [94].

For the preparation of QSSEs, three methods are sometimes used: (i) solidification of LEs to form thermoplastic polymer electrolytes or thermosetting polymer

electrolytes by using organic polymer gelators; (ii) solidification of LEs to form composite polymer electrolytes by using inorganic gelators, such as SiO_2 , nanoclay powder; (iii) by using organic polymer or inorganic gelators for the solidification of ionic LEs [62]- [95].

2.5.3 Quasi state transport materials (SSTMs)

Stability is also the key issue for QSSEs, as the electrolytes still contain solvents and are usually thermodynamically unstable. Solvent exudation is inevitable during long storage or exposure to air. All SSTMs have more advantages over LEs and QSSEs in this respect, especially in the actual large-scale application of DSSCs. Several materials, including ionic conductors, inorganic hole-transport materials and organic hole-transport materials have been developed to substitute LEs or QSSEs with SSTMs [96]- [97].

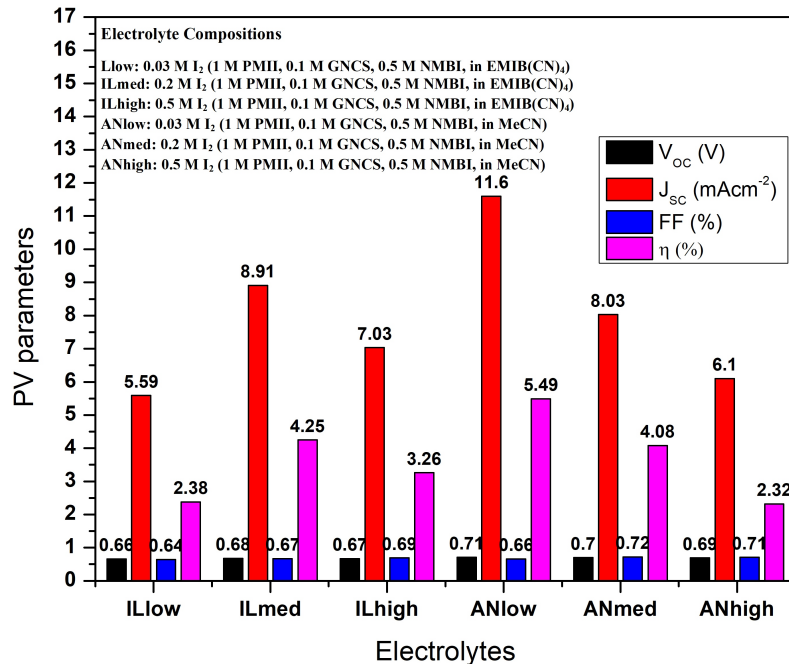

Figure 2.5: PV performance of DSSC based on electrolyte compositions [98]

Moreover few of the researcher's work also investigated the effects on DSSCs based on low-viscous, binary ionic liquids (IL) and organic liquid solvents with varying iodine concentrations ($[\text{I}_2]$) and iodine-to-iodide ratios in electrolytes. Using intermediate and low $[\text{I}_2]$ in ionic liquid-based and acetonitrile (AN) based electrolytes respectively; optimum J_{SC} and η were achieved. Photo electrochemical and Raman-

spectroscopic measurement results show that the optimal $[I_2]$ needed in these two types of electrolytes is influenced by both I_3^- mobility and chemical availability. The higher $[I_2]$ required for the IL-based electrolytes partly compensate for these effects, although negative effects from higher recombination losses and light absorption of I_2 containing species start to become significant [98].

2.6 Synthesis routes for Metal Oxides (TiO_2)

2.6.1 Circular shape TiO_2

By the sol-gel process, hierarchically ordered titanium dioxide nanoparticles were successfully synthesised. Powder X-ray diffraction, UV-Vis spectroscopy, (BET) Brunauer Emmett Teller method, Barrett Joyner Halenda (BJH) analysis, field emission scanning electron microscopy, high-resolution transmission electron microscopy and energy-dispersive X-ray analysis were subjected to the synthesized nanoparticles.

The pattern of powder X-ray diffraction shows that the particles obtained are of good crystallite quality in the anatase process. The isotherms of nitrogen adsorption and desorption show that the prepared material has an area of $31,71 \text{ m}^2\text{g}^{-1}$ and the study of pore size distribution shows that the average pore diameters of mesoporous TiO_2 nanostructures are 7.1 and 9.3 nm. In the ultraviolet field, the UV-Vis DRS spectrum shows that the TiO_2 nanoparticles are absorbed. The nanoparticles' optical band gap is 3.2 eV. Morphological experiments indicate that the particles' morphology is circular in shape. Energy-dispersive X-ray spectrum study confirmed the elemental compositions of TiO_2 nanoparticles. With open circuit voltage (V_{OC}), short circuit current (I_{SC}) and fill factor (FF) of 0.607 V, $13.206 \text{ mA cm}^{-2}$ and 42.56 %, the conversion efficiency of the solar cell was 3.415 % [99].

2.6.2 TiO_2 microsphere

For a lot of applications, especially in the field of solar cells, TiO_2 microspheres (MS) are of great interest. TiO_2 microsphere based solar cells often exhibit superior photovoltaic performance due to their unique microstructure and light scattering

effect. Hence it is important to explore new suitable TiO₂ microspheres for high-efficiency solar cells. The simple one-pot solvothermal method for synthesizing TiO₂ microspheres using acetone as a solvent is synthesized by the researchers. The TiO₂ microspheres as prepared are made of densely intertwined nanocrystals and have a high specific area of up to 138.47 m²g⁻¹. The TiO₂ microsphere-based DSSC, like the photoanode, provides greater dye loading and light adsorption capability, longer electron lifetime, resulting in higher short circuit current value and superior efficiency of power conversion compared to Dyesol (DSL) 18 nm TiO₂ nanoparticles paste. Finally, the DSSC based on the TiO₂ microsphere was optimised by adding a sublayer of TiO₂ nanocrystals and post-treatment TiCl₄, giving a 10.32 % high power conversion efficiency. Comparison of the photovoltaic properties measured under 1 sun illumination and dye adsorption capacities for TiO₂ MS and DSL-18 based DSSCs is listed in Table 2.5 [100]

Table 2.5: TiO₂ MS and DSL-18 based DSSCs PV performance [100]

Cell	Thickness	Dye loading (10 ⁻⁸ molcm ⁻²)	J _{SC} mAcm ⁻²	V _{OC} (V)	FF	η
TiO ₂ MS	7 μm	9.69	13.89	0.761	73.77	7.80
DSL-18	7 μm	8.82	11.88	0.759	74.81	6.76

2.6.3 Spherical TiO₂

The spherical titanium glycolate precursors are subjected to a rapid microwave treatment via ethylene glycol-mediated sol gel process to synthesize porous anatase TiO₂ spheres ranging from 150 to 250 nm in size. It explored the effects of different experimental conditions on the formation of precursors of titanium glycolate and final spheres of TiO₂. A dye-sensitized solar cell (DSSC) assembled as photoanodes with the as-synthesized porous TiO₂ spheres exhibits 5 % energy conversion efficiency, almost 40 % higher than that provided by the standard commercial Degussa P25 TiO₂ nanopowders [101].

2.6.4 TiO₂ Anatase powder

Dye sensitized solar cells (DSSC) may be an alternative to solar cells based on silicon that is economically feasible and technically simpler. The most effective photoelectrode for DSSC is known to be films of nanocrystalline titanium dioxide (TiO₂). TiO₂ anatase phase powder, synthesized in an acidic environment, was used for this analysis. The average nanoparticle diameter was nearly 20 nm and the surface area of the BET was 64.68 m²/g. By varying the proportion of TiO₂ powder, α -terpineol and ethyl cellulose (EC) in their composition, different TiO₂ pastes were prepared. Using the doctor blade, the TiO₂ paste was cast on the fluorine doped tin oxide (FTO) coated glass surface to prepare TiO₂ film photo-electrodes. By comparing the conversion efficiencies of the DSSCs produced with the 18 μ m thick photo-electrode, the composition of the paste ingredients was optimized. The outcome of this study may be crucial for the easy preparation of reliable TiO₂ paste for use in DSSC. Composition of different pastes of TiO₂ nanoparticles used for the fabrication of DSSC as listed in Table 2.6. The pure EC content was only 15 % in the EC gel whereas rest of the 85 % was α -terpineol [102].

Table 2.6: PV performance of DSSC prepared from different TiO₂ by varying proportion of TiO₂ powder, α -terpineol and ethyl cellulose (EC) in their composition [102]

S.No	TiO ₂	ethyl cellulose (EC)(wt.%)	Total ethyl cellulose (EC)(wt.%)	Total α -terpineol (wt.%)	Pure EC (wt.%)	η (%)
1	20	20	60	77	3	4.6

3	26	15	59	71.75	2.25	7.27
4	29	12.5	58.5	69.13	1.88	6.25
5	32	10	58	66.5	1.5	5.1

2.7 Improvements in photoanode

The main function of the WE is to harvest the incident photon efficiently and to provide transportation path for the charge carriers with minimum recombination centers. WE should also capable to bind the dye molecules at TiO₂(metal oxide)

surface in order to collect photo generated efficiently at near the Dye/TiO₂ interface upon light illumination. The metal oxide layer of WE should inherit the following characteristics to achieve excellent electron generation and transportation process.

- Surface area of metal oxide nano particles should be large in order to increase the dye loading capacity of WE
- Follow the transparency for visible spectrum (400nm – 700 nm) so that losses of incident photon can be minimized
- LUMO level of the dye molecules must lie above the CB of the TiO₂ (metal oxide) for electron injection efficiently
- Sufficiently high electron mobility to achieve effective electron transportation process across network of TiO₂ nano particles
- Inactive to electron recombination across TiO₂/electrolyte interface

The photoanode is considered as a imperative component of DSSC for anchoring dye molecules for electron transfer upon light illumination. The better electron transport is required to minimize the electron recombination to obtain efficient DSSCs. Faster electron injection process (dye to TiO₂ CB) results high performance DSSCs with rapid electron transport. An efficient research has been continuously carried on high specific surface area, light scattering effect, enhanced charge-collection η and rapid charge transport for improving the performance of TiO₂ based photo-electrodes. The spatial distribution of semiconducting particles of WE such as microstructure, particle size, pore size and porosity plays an vital role in modulating the PV characteristics of DSSC. The screen printing method and doctor blade technique can be employed to coat the oxide film on the FTO glass of WE. The nature of deposited oxide film critically depends on the technique of film coating as well as on the physical properties of the respective slurry paste (e.g., viscosity, binder type, solvent type, etc) which may further affects the performance of DSSC. Increasing electrode thickness also enhances the light absorption hence increases the charge generation which impact on the cell performance. Few of the works done in this area are listed below.

2.7.1 Improvements in nano structures of photoanode

A simple solution deposition method without the need of seed or fresh deposition solution was used to synthesize ZnO micro-flowers for the application DSSC fabrication with ZnO PE. The ZnO micro-flowers/nanoparticles bilayer film-based DSSC reports much higher light harvesting light harvesting efficiency, lower resistance and longer electron lifetime as compared with the ZnO nanoparticles film-based DSSC. Moreover 47 % of improvement in η is observed for monodispersed aggregates ZnO layer alone due to the scattering effect of ZnO micro-flowers layer [103].

Dye-sensitized solar cells were synthesized and applied to Echinoid-like particles (DSSCs) to enhance the Dye-loading by increasing their surface. In addition, diffuse reflectance showed that the micron size of echinoid-like particles caused a scattering effect. The increase in J_{SC} resulting from the increase in dye loading compensated for the reduction in V_{OC} and resulting improvement in η from 6.63 % to 6.74 % [104]. Work in DSSC's Titania photoanode has successfully assimilated carbon nanotubes (CNT) with a hierarchical porous structure synthesized by process called controlled phase separation [105]. The results showed lower series resistance, efficient charge injection, and improved electron life time. For effective DSSCs, the charge transport and separation properties are desirable. Moreover, the addition of CNTs to the Titania matrix increased the critical thickness with which the cell could achieve maximum performance.

DSSCs were fabricated using photoanodes made from graphene TiO_2 nanocomposites to investigate the dependency of the size of graphene sheets on the cell performance. It is reported that smaller graphene sheets improved the dye adsorption, leading to higher. The DSSC incorporated with graphene sheets of 184 nm exhibited the largest enhancement in efficiency (increased by 49 %) as compared to the cell without grapheme [106].

A TiO_2 film of double layered nano structure employed for the development of photoanodes for DSSCs [107]. The performance of the DSSCs fabricated of composite photoanodes of TiO_2 nanoparticles (NPs)/NPs (TiO_2 P-P), TiO_2 NPs/nano-belts (NBs) (TiO_2 P-B), TiO_2 NBs)/NBs (TiO_2 B-B) is also investigated. It is observed that TiO_2 NB layer improves the light scattering and the TiO_2 NP layer improves the dye absorbing capacity of the film which further improves the overall η of DSSC

to 4.81 %, 3.55 % and 0.36 % for TiO₂ P-P, TiO₂ P-B and TiO₂ B-B respectively. Various research works discussed the growth mechanism of zinc oxide (ZnO) samples of different morphologies. It reports electrochemical deposition (ECD) technique to grow ZnO samples by controlling the concentration of precursors. The influence of the morphology of ZnO samples on the performance of the assembled DSSCs based on ZnO working electrode (WE) by investigating their PV characteristics, quantum efficiency (QE) and electrochemical impedance spectrum (EIS).

By using ECD technique along with controlling the concentration of precursors, ZnO sample of different morphologies eg. film, nanowire and nanosheet are studied and employed for the DSSCs applications. It is reported that the DSSC fabricated with ZnO nanowire array as WE shows improvement in dye absorption and also enhanced the rate of photon utilization which further provides the rapid collection channels for the photo-excited carriers. Therefore, the PV improves the PV performance and η of the DSSC based on ZnO nanowire (WE) [108].

Table 2.7: Summary of performance parameters on improvements in nanostructures of photoanode.

The hierarchical architecture of ZnO nanorods-nanosheets (NR-NS) consisted of long nanorod backbones, and thin nanosheet branches were synthesized by using a two-step hydrothermal growth process for the application of DSSCs on the zinc foil substrate. The photovoltaic results showed that the ZnO NR-NS hierarchical architecture-based DSSC short-circuit current density increased significantly com-

pared to that of DSSC based nanorods, which was due to higher dye loading and superior light scattering within the photoanode of the NR-NS hierarchical architecture. As a result, the η of the hierarchical architecture based DSSC based on ZnO NR-NS increased by 90 % compared to that of the DSSC based on nanorods [109]. Using a simple hydrothermal process, TiO₂ films with various morphologies directly grown on fluorine-doped tin oxide (FTO) substrates were prepared. Assembled DSSC with TiO₂ microsphere films grown as a photoanode on the FTO substrate achieves an overall photoelectric conversion efficiency of 1.94 % and I_{SC} of 5.12 mAcm⁻² due to the rough surface, which is higher than that of the nanorod array and DSSCs based on nano flower [110] (see summary in Table 2.7).

2.7.2 Seed layer and preparation methods

Application of mesoporous TiO₂ for DSSC is widely preferred in order to implant high density of dye molecules onto the surface of TiO₂ nano particles for enhancing the photon absorption. DSSC sometimes also suffers from problem of short circuit between TCO and liquid electrolyte due to highly mesoporous property of TiO₂. This undesirable phenomenon can be regulated by employing a compact layer of sol-gel processes TiO₂ nano particles of size 5-10 nm. Later sol-gel processes were replaced by RF sputtered TiO₂ films.

A vital component for improving the η of DSSCs based on of ZnO nanorods array is the dye adsorption which can be investigated by the dye adsorptivity factor of single nanorod and the density of nanorod arrays.

With increasing seed layer thickness, the density of the nanorod arrays gradually increases, further forming large surface area for dye adsorption efficiently. Furthermore, the increased dye loaded molecules on the surface is the result of continuous increasing the number of desorption/adsorption cycles. As a result, it is noted that the photocurrent densities (J_L) and η of ZnO nanorod array-based DSSCs have significantly improved [112].

By combining the commercial titanium powder P-25 with a titanium sol gel, the TiO₂ photoanode was prepared. Two monolayer photoanodes with ultrasonic and without ultrasonic TiO₂ pastes of approximately the same thickness were prepared and their results were compared with the overall performance of the DSSC cells. The

ultrasonic TiO₂ photoanode was efficient for DSSCs where the improvement of the overall energy conversion efficiency is achieved for the sonicated TiO₂ photoanode with the presence of PEG was almost double that of the non-sonic film [113]. Few of the key improvement reported in the seed layer deposition are listed in Table 2.8.

Table 2.8: PV performance of DSSC with respect to experiments conducted on seed layer (SL).

S.No	Fabrication of Photo-anode	J_{SC} mAcm ⁻²	V_{OC} (V)	FF	η (%)	Ref.
1 thickness of SL	ZnO nano rod based DSSC					[112]
	10 nm	1.85	0.55	0.37	0.38	
	20 nm	1.95	0.55	0.37	0.39	
	50 nm	2.05	0.55	0.36	0.40	
	75 nm	2.10	0.55	0.36	0.42	
	100 nm	2.08	0.55	0.36	0.42	
2 Type	Monolayers photoanodes, with and without ultra sonic treatment					[113]

	Without ultrasonic treatment	3.68	0.63	0.561	1.31	
3 Combination	Optimized spin coating process for seed layer formation					[114]
	Bare-FTO+DT51	5.88	0.444	0.47	1.21	
	SC2+DT51	6.90	0.515	0.63	2.23	
	SC4+DT51	6.94	0.494	0.55	1.87	
	SC6+DT51	6.08	0.496	0.58	1.76	

Using an alcoholic TiCl₄ solution, an optimized spin coating method was created and correlated to the final properties of the layer. To achieve a uniform layer, the physicochemical features of the precursor solution and the spin coating parameters have been optimized. The results were compared with those obtained using a traditional dip coating technique, showing that blocking layers are produced by the newly developed spin coating process, resulting nearly 84 % of improvement in η [114].

Using tetrabutyl titanate as the starting material, nanocrystalline TiO₂ was prepared through hydrothermal synthesis. The reaction temperature changed from 120 °C to 160 °C with a constant reaction time of 12 h, and the pH value of the reaction medium ranged from 1 to 9. The experimental results showed that the pH value influenced the phase of the powder, while the particle size depended on the temper-

ature of the reaction. Pure TiO₂ anatase was obtained at a pH of 3. The DSSC's solar energy conversion efficiency provided with pure TiO₂ anatase prepared at 140 °C was reported to 3.64 %, which was higher than that prepared under any other conditions with TiO₂ as listed in Table 2.9. The TiO₂ (P25) purchased was used for comparison to make a DSSC. It turned out that the efficiency of all TiO₂ DSSCs prepared by hydrothermal synthesis was greater than that of P25 [115].

Table 2.9: PV parameters of assembled DSSCs from TiO₂ prepared at 140°C under different pH values [115]

S.No	Samples	Anatase content, (%)	V _{OC} (V)	J _{SC} mAcm ⁻²	FF	η (%)
1	pH = 1	81	0.71	4.62	0.66	2.17

5	pH = 9	85	0.72	6.44	0.64	2.98
6	P25	75	0.68	5.65	0.55	2.12

Graphene–titania films were developed by aerosol deposition with varying graphene concentration from 0.1 to 1.0 wt % to produce G–TiO₂ films for DSSC application as listed in Table 2.10. The optimal concentration was reported at 0.3 wt %, which reduced the rate of recombination, favoring the formation of pairs of photo-generated electron-holes. The conversion efficiency decreased owing to higher absorption of light by graphene present on the surface, thus reducing the generation of electron–hole pairs for concentrations higher than 0.3 wt % [116].

Table 2.10: Parameters for DSSCs based on different graphene concentrations [116]

S.No	Sample (wt %)	V _{OC} (V)	J _{SC} mAcm ⁻²	FF	η (%)
1	Pure	0.68	7.20	64.26	3.14
2	0.1	0.75	8.92	60.95	4.08
3	0.3	0.75	10.93	61.26	5.02
4	0.5	0.74	10.90	59.12	4.77
5	0.7	0.72	9.27	60.14	4.00
6	1.0	0.69	8.67	60.47	3.62

For parallel modules, flexible dye-sensitized solar cells (FDSSCs) are introduced with varying numbers of arrayed TiO₂ WE. Instead of a single cell, FDSSCs are

typically manufactured as a module type to improve the PV characteristic parameters and η are listed in Table 2.11. The general modules of the FDSSCs are designed as parallel strip-shaped and parallel forms of interconnection, and there are some advantages, such as simple production, low cost and simple structure. The active areas of FDSSCs are the same (0.48 cm^2) in this recorded study and have different amounts of thin TiO_2 films.

The single strip-shaped (TSP) WE of TiO_2 have a higher internal resistance than thin films of TiO_2 . The best way to solve the problem, higher internal resistance than single TiO_2 thin film, is therefore to produce the different quantities of arrayed flexible TiO_2 WE. As a result, the FDSSC, which has the WE of the TSP TiO_2 , has a higher η (0.25 %) than other TiO_2 thin films [117].

Table 2.11: Performance parameters of FDSSCs with different quantities of TiO_2 thin films [117]

S.No	Different quantities of TiO_2 thin films	V_{OC} (V)	J_{SC} mAcm^{-2}	FF %	η (%)
1	single strip shaped	0.78	0.56	35.06	0.15
2	double strip shaped	0.70	0.86	36.19	0.22
3	triple strip shaped	0.71	1.11	31.67	0.25

TiO_2 films of about 100 nm thickness were RF-sputtered at room temperature on indium-tin-oxide coated glass substrates and used as the compact layer for fabrication of DSSCs. The PV characteristics of the DSSCs with AM 1.5 illumination showed a very high V_{OC} of 780 mV, a high R_{SH} of 400 $\text{K}\Omega$, $J_{SC} = 12.3 \text{ mA/cm}^2$ and $\text{FF} = 61 \%$, while the V_{OC} , R_{SH} , J_{SC} and FF of the DSSCs manufactured with traditional sol-gel processed TiO_2 compact layers were 520 mV, 463 $\text{K}\Omega$, 5.4 mA/cm^2 and 46 % respectively [118].

2.7.3 Experiments with semiconductor materials

It is observed that absorption of visible light spectrum can be increases by doping narrow band gap semiconductor to TiO_2 . When a narrow-band meso-porous TiO_2 electrode to enhance the light harvesting η of DSSCs. Few of the metal chalcogenide semiconductors such as cadmium sulfide (CdS), cadmium selenide (CdSe), lead sulfide (PbS), and CdS/CdSe are used to fabricate quantum dot-sensitized solar cells

(QDSSC).

The various working electrodes based on quasi-core-shell TiO_2/PbS composites are fabricated by a simple hydrolysis process. Results investigated that apportion spectra is shifted from UV to visible range. Various experimental works (samples F1-F11) were carried out consisting different proportions of the elements (by weight) and performance of the various associated DSSCs is listed in Table 2.12 [119].

Table 2.12: PV parameters of DSSCs from different experiments. [119]

S.No	Experimental substrate	V_{OC} (V)	J_{SC} mAcm^{-2}	FF	η (%)
1	F1	0.65	13.86	0.57	5.11

A new idea for improving the efficiency of TiO_2 DSSC by proposing of a double-layer film doped with various Zinc (Zn) ions, with a variety of morphologies and phase arrangements. The light absorption and scattering is improved by low energy bandgap. The PV parameters of DSSC assembled for TiO_2 mono layer (compositions of Anatase and Rutile) and TiO_2 double layer (as light scattering layers) with various Zn atomic % along with dye loading are listed in Table 2.13 and Table 2.14 respectively [120].

The thickness dependent performance of TiO_2 passivated DSSC grown by sputter technique on F-doped SnO_2 (FTO) electrode as listed in Table 2.15. The idea of implementing this technique is to investigate the optical transparency, surface roughness and passivation properties of the TiO_2 layer passivating the FTO electrode which are the function of thickness of the TiO_2 passivating layer. More over it is reported that the η of the cell is critically dependent on the thickness of RF sputtered TiO_2 layer inserted between FTO electrode and nanoporous TiO_2 layer. Hence 50nm thick TiO_2 passivating FTO electrode showed the maximum power η

of 4.42 % due to effective prevention electron back reaction (electron/electrolyte recombination) as shown in table below [121].

Table 2.13: PV parameters for fabricated mono layer DSSC [120]

S.No	Experimental substrate	V_{OC} (V)	J_{SC} mAcm^{-2}	FF	η	Zn at%	Adsorbed dye (10^{-8}cm^{-2})

2.8 Improvements in counter electrode (CE)

Various researches to develop Platinum (Pt) free counter electrode (CE) are carried out in order to minimize the fabrication cost of DSSC. In this research area CEs were produced using graphene nanoplatelets (GNPs) or multi-wall carbon nanotubes (MWCNTs) or various weight % of hybrid GNPs and MWCNTs mixtures. These materials have been dispersed using PEDOT: PSS polymer and then deposited on

FTO glass as well as on a non-conducting glass substrate by a drop casting method. Results show the improvement in η and life of CE (see Table 2.16).

Researchers also examine DSSCs incorporated with carbon nano-onions as CE. The candle flame deposition technique is carried out to deposit synthesized carbon nano-onion nanoparticles on Cu sputter coated glass substrates (see Table 2.16). DSSCs performances indicated that the carbon nano-onion based CE exhibit comparable performances to conventionally used Pt and could be scaled up in industrial production [122].

Table 2.16: PV performance of DDSC by modification in CE.

S.No	CE Proposed idea	J_{SC} mAcm ⁻²	V_{OC} (V)	FF	η (%)	Ref.
1 Type	Counter electrodes using nano particles					
	C hybrid/glass type CE	8.275	0.64	0.47	2.48	
	PEDOT:PSS/glass type CE	0.686	0.4	0.4	0.11	
	GNPs/glass type CE	2.46	0.6	0.34	0.51	
2	Carbon nano onion CE	7.65	0.68	0.65	3.39	[122]
3 Type	Fabrication of transparent CE					[123]
	Pt nano particle based CE	11.24	0.82	0.67	6.17	
	Sputtered Pt based CE	10.84	0.815	0.72	6.36	

It is reported that a highly transparent Pt CE can be achieved by spray coating of Pt nano-particles (NPs) on pre heated substrates and 86 % reduction in the consumption of Pt is observed during the experimental work which further reduces the cost of fabrication of DSSC [123].

A composite photo electrode with Pt nanoparticles (NPs) is deposited on three dimension FTO glass. This 3D FTO conductive grid was fabricated as the CE of DSSC, which exhibits larger electrochemical active surface area (9.54 m²/g) and lower charge transfer resistance (2.1 Ω) in iodide/triiodide (I⁻/I₃⁻) redox electrolyte than the conventional planar CE which further results 14 % higher η [124].

A nano-structure-based Pt counter electrode was manufactured to increase the performance of the DSSC by assembling silver (Ag) NPs on glass substrates and depositing a thin Pt layer. DSSCs with nano-particulate structure have improved the overall PV characteristics [125].

2.9 Effect of annealing on PV response

The improvement in the photoelectrochemical properties of the manufactured cell sintered at elevated temperatures can be due to (1) an increase in crystallinity which is beneficial in the geometry of anchoring dyes leading to faster electron injection [126], (2) an increase in the size of the grain leading to an improvement in the scattering of light and a decrease in the interconnection between particles [127]. In addition, the increase in annealing temperature increases the injection of electrons by enlarging the coefficient and lifetime of electron diffusion. At more than 500 °C, the overall photovoltaic characteristics were drastically reduced (see Table 2.17). This may have been caused by the reduction of the substrate's conductivity due to conductive film degradation [128].

Table 2.17: Impact of annealing temperature variation on DSSC PV performance [128]

Annealing temperature (°C)	V_{OC} (mV)	J_{SC} mAcm ⁻²	FF	η (%)
350	522	0.43	0.36	0.081
400	496	0.52	0.32	0.084
450	564	0.66	0.29	0.11
500	525	0.59	0.24	0.082
550	522	0.58	0.24	0.079

2.10 Encapsulation of DSSCs

UV radiation and environmental deterrents can degrade semiconductor photoelectrodes, photosensitive dyes (synthetic pigments and complexes), and other nanomaterials used in photocatalytic water splitting. The equipment's encapsulation requires the appropriate non-corrosive (with electrical exposure), non-conducting, extremely transparent barrier material. Therefore, the barrier material should possess some of the crucial properties which help the effective functioning of these devices to be used in the previously discussed specific applications [129]- [130].

- Flexibility: The encapsulant material, as well as the device substrate, must be flexible enough to prevent cracks formation.

- Hermetic: The device must be totally sealed from the outside environment, safeguarding it from external degradants such as O₂, H₂O, chlorofluorocarbons, and UV rays.
- Extremely low gas permeability: The encapsulant should act as a barrier against penetrating gases such as oxygen and moisture.
- Stability: The encapsulant must be stable in terms of dimensions, chemical properties (non-corrosive), thermal properties, and electrical properties.
- Processing ease: Processing compatibility with the final product for integration is a critical criterion in terms of energy and economic savings.

As a result, several organic and inorganic materials are being studied for their usage as encapsulants in order to meet these specific requirements.

A new family of Fe_{1-x}S/Fe₃C-NCNTs hybrids, with the architecture of “Fe_{1-x}S loading on Fe₃C-encapsulated and N-enriched carbon nanotubes”, was strategically established by a facile in-situ carbonization-sulfurization process and developed as CE catalysts in DSSCs. The electrochemical results showed that the hybrids delivered an excellent catalytic activity for I₃⁻ reduction with a low charge transfer resistance of 1.56 Ω, and the Fe_{1-x}S/Fe₃C-NCNTs CE based DSSC achieved a high power conversion efficiency of 8.67%, which is superior to 7.75% of the device based on traditional Pt CE. Furthermore, the DSSC with Fe_{1-x}S/Fe₃C-NCNTs hybrid CE also showed an extraordinary electrochemical stability in long-term operation.

The impact of cellulose nanocrystals (CNCs) made from bacterial cellulose (BC) and nanofibrillated cellulose (NFC) on the structural properties of polyurethane (PU) composites are also investigated [131]. The feasibility of using the polymer composite to encapsulate dye sensitised solar cells piqued the researchers' curiosity. Both CNCs were esterified before being mixed with the polyurethane in a solution method. In this study, the strongest PU nanocomposite film was obtained when 2 wt % of the esterified BCNCs was applied to the polymer matrix. The results from thermal analysis indicate that the onset temperature for decarboxylation step of the polymer increased after adding the modified CNCs. The water vapor transmission rate of the PU films was rapidly dropped by 56% when 0.5 wt % of the esterified BCNCs was added. Percentage visible light transmission through the polymer com-

posite films was above 80%, regardless of the type and concentration of the CNCs. By encapsulating dye sensitized solar cells with the polymer/esterified B-CNC composites, it was found that the lifetime of the devices can be extended by more than 336 h without losing its initial power conversion efficiency.

Hence from the literature survey it is understood that the optimum electrolyte concentration and type of electrolytes are two vital electrolyte parameters in order to control and optimize the performance of the DSSC. Improving the Dye regeneration capability of electrolytes and recombination kinetics enhances the dye regeneration efficiency of the solar cell. Electrode thickness can be considered as critical component which determines the light harvesting capability of DSSC device. EIS curve fitting technique can be one of the efficient methodology to investigate the charge transport properties for the evaluation of electron recombination kinetics and their life time across TiO_2 /electrolyte interface.

Controlling the electrode (WE) thickness, slurry or paste preparation and composition, particles shape, size, porosity and its distribution in the oxide film can be treated as major factors which have significant potential in order achieve optimum performance of DSSC. The discussed modifications can be considered in order to modulate the physical and chemical properties of WE to enhance PV performance of DSSC.

The variations of morphology, size and crystal phase of TiO_2 micro/nanostructures have potential to enhance the performance of the DSSC by improving dye loading, superior light scattering ability, and/or faster electron transport and longer electron lifetime. Hence by finding the high yielding routes for synthesis of various morphologies for TiO_2 nanoparticles with suitable band gap can be considered as another approachable method to improve the cell performance and same is discussed in chapter 3.

Chapter 3

Facile one pot hydrothermal synthesis of nanorice-like TiO_2 for an efficient dye sensitized solar cell (DSSC)

3.1 Introduction

Apart from traditional applications, nanocrystalline TiO_2 intrinsically possesses multi-functional properties such as environmental photocatalysts (polluted airs, wastewaters, self-cleaning windows having antimicrobial activity); efficient electrodes for photovoltaic, photo-electrochromics and gas sensing devices etc. In this matter, several physical techniques and chemical approaches have been successfully used to prepare various crystal forms and anisotropic shape nanosize crystalline TiO_2 materials [132]- [134]. Among these chemical approaches, a low temperature hydrothermal (HT) reaction is widely preferred because of its simplicity, low-cost, and ability to readily control the physicochemical properties of material need to be synthesized e.g. crystallinity, size and morphology of particles, and textural Brunauer-Emmett-Teller (BET) features (surface area; pore's shape/size and volume). Such controlled desired physicochemical properties of material can be achieved by making a tailored combination among the reaction variables viz. time, temperature, type of precursors (pristine or chemical modification), type of solvent and pH

controlling agent etc.

Here, in this chapter, we report a simple and facile low temperature HT synthesis of high crystalline nanorice-like TiO₂ powder, whose pore's size and volume are though relatively larger than to a commonly exploited model (Degussa, P-25) powder, yet both these TiO₂ powders have more or less comparable average particles' size and BET surface-area. As the nanoparticles of these TiO₂ powders differs in their shape (P-25 is nearly spherical) so such shape dependent superior charge transfer properties of nano-rice like TiO₂ is highly reflected in an easily implemented a low cost DSSC device technology, which could fulfil our future needs of clean energy [135]. Under global light illumination (1 sun, AM 1.5 G), and identical electrode fabrication and DSSC assembling conditions, cell made of nanorice-like anatase TiO₂ easily gave a solar to electric conversion efficiency (η) ca. 6.49 %, an enhancement of ca. 19 % with respect to that of a reference cell made of a commercially available and commonly exploited benchmark TiO₂ (Degussa, P-25).

3.2 Adsorption of a gas on the material's surface by BET Analysis

The basic element of the theory of BET is the adsorption of a gas (adsorbate) on the surface of the material. The physical adsorption due to the Vander Wall forces existing between the gas molecules and adsorbing surface and chemical adsorption due to formation of resultant products by chemical reaction solid surface and gas molecules are the two major type of adsorption phenomenon [136]- [138]. All the adsorbed molecules forming the layer are in contact with the surface of the adsorbent [139]- [142], [144]- [145]. In addition to this it is possible to compare the net amount of gas adsorbed with its surface area of the adsorbent material [143]. In a closed-packed structure, this coverage can happen when molecules are close to each other or when scattering across the surface as well. Solid and gas interacting force keeps the gas molecules on the surface of the adsorbent material.

On the other side, more than one layer of gas molecules is generated with multilayer adsorption, so it can be easily stated that all the gas molecules are not available to make the contact with the top surface adsorbent layer. Therefore, gas molecules

start interacting to each other in their vapor phase. These interaction energies of the vapor phase are close enough to match the energies in solid-gas interaction that contributes to the gas adsorption at the top of gas molecules that are already adsorbed on a solid's surface. As a consequence, a gas condenses into a liquid phase [146]. When the temperature of the absorbent surface is lower than the critical temperature of gas molecules, multilayer adsorption is a common phenomenon.

The pressure increases until it reaches to a value close to the bulk vapor pressure during the formation of adsorbate molecules [146]. After monolayer (ML) and subsequently ML adsorption on the pore walls, capillary condensation signify that pores are filled with condensed gas. The increased Vander Waals interactions between gas molecules at confined space of pores leads to vapor-liquid phase transitions below the bulk liquid's saturation vapor pressure (P_{sat}) [137]- [147]. From BET analysis its can be assumed that each adsorbed layer is not interfering to it next layer during the ML adsorption. Hence Langmuir equation can be applied on each adsorbed layer [148]- [149]. Molecules act as absorption sites in the layers below the initial one The BET equation is established as given by eqn. 3.1 [147].

$$\frac{P/P_0}{n(1 - P/P_0)} = \frac{1}{n_m C} + \frac{C - 1}{n_m C} \left(\frac{P}{P_0} \right) \quad (3.1)$$

3.2.1 N₂ gas Adsorption Technique

Adsorption can be defined as the "tendency of one component of the system to have a higher concentration at the interface than it has in either of the adjacent bulk phases". Considering a solid-fluid type system where the fluid density continuously increases near the region of solid fluid interface. Adsorption phenomenon is further categorized into physisorption and chemisorptions illustrating whether the gas molecules and the surface layer are interacting through chemically interactive forces or physically interactive forces in nature. Experiments to analyze the physisorption process are carried out with various gases and under various sets of pressure-temperature conditions. Conditions like low temperature and higher pressure are also preferred for efficient adsorption and these experiments are capable to investigate the surface area and pore's structure of the porous sample material (textural properties).

Now day's nitrogen gas (N_2) at 77 K is normally used for characterize the textural properties and to analyze mesoporous nature of the sample (TiO_2 etc). Gases like carbon dioxide at 273 K, argon at 87 K, and krypton gas at 77 K may also be used for the characterization to study the adsorption process. Moreover analysis of adsorption taking place at higher pressures, where the gas is in the supercritical stage, provides the information on the nature of the surface of the sample and its gas adsorption potential, as well as information on the surface area and surface properties of the sample (TiO_2 etc.).

3.2.2 Experimental Procedure and fundamentals principles of BET

In this procedure, a discontinuous static volumetric method is used to investigate the amount of gas adsorbed on the sample by conducting experiments on Micromeritics ASAP 2010TM instrument after the preparation of sample. Prior to the analysis, degassing of the sample (1-2 gm) inside the tube is done by creating vacuum ($<10 \mu\text{m Hg}$) and then heating it at 200 °C for 24 Hrs. Further heat treatment under vacuum conditions is done until the sample out-gassing rate reach below to 0.005 Torr/min over a 15 minute interval ($\sim 16-24$ hours). The dead volume of the tube is measured volumetrically by using helium before performing experiment for adsorption isotherm. The helium evacuation is performed from the sample tube and the tube is then kept in cryogenic liquid nitrogen (LN_2). Afterwards, the sample tube is dosed with N_2 (of known amount) with precisely controlled pressures. The amount of adsorbed gas on the solid surface at constant temperature is measured at discrete pressure (P) steps over the relative equilibrium pressure P/P_0 range of 0.0075 to 0.995.

After increasing the pressure up to condensation pressure (branch of adsorption), the pressure reduces from the pressure point P_0 (branch of desorption). During this operation data sets are collected and reported as the profile of isotherm related to adsorption process. This results in the characteristics where quantity of gas adsorbed per mass (moles or volume (cm^3/g)) is plotted as a function of P/P_0 .

3.2.3 Qualitative Interpretation of N₂ Isotherm Profile

Combined analysis of isotherm's shape and its hysteresis pattern is considered as vital characteristics for the interpretation the nature of physisorption mechanism and solid-gas interaction which are capable for the qualitative prediction of the variety and type of pores present in the adsorbent. Along with four types of hysteresis patterns (H1-H4), IUPAC further estimates six types of adsorption isotherms (Type I-VI) [19] where three are discussed in detail in this chapter which are particularly critical reason behind the formation of isotherms for unconventional gases and oils as shown in (Figure 3.1) [150]- [151]. Different mesopore shapes are characteristic of the various hysteresis patterns H1-H4.

3.2.3.1 Isotherm: Type I

A microporous (MP) adsorbent shows a concave-shaped isotherm for the ranges $P/P_0 < 0.01$ until it reaches a plateau. For this range of relative pressure relative pressure isotherm shows very high adsorption (see Figure 3.1(a)). The small micropores result in overlapping the possible adsorption fields of opposite walls. This overlapping potential energy creates an increased interaction of adsorbent-adsorbate resulting in high uptake of adsorption at low relative pressures. This phenomenon is called as the filling of micropores. The limited uptake (plateau) depends on the sample's cumulative accessible volume of micropores.

3.2.3.2 Isotherm: Type I

A fully reversible isotherm (Figure 3.1(b)) can be exhibited by a non-porous or macroporous (MaP) substance where adsorption and desorption follow exactly the same direction. At lower ranges of relative pressures ($P/P_0 < 0.2$), these isotherms initially have a concave form followed by a linear area and eventually a convex form similar to the P/P_0 axis at higher relative pressure ($P/P_0 > 0.4$). This isothermal profile reflects a mechanism of gas monolayer-multilayer adsorption on the open and stable solid surface.

3.2.3.3 Isotherm: Type IV

A characteristic hysteresis loop would have prominent mesoporous (MeP) content (Figure 3.1(c)), which is consistent with capillary condensation and evaporation taking place in mesopores. The isotherm profile is identical to Type II isotherms at lower ranges of relative pressure ($P/P_0 < 0.4$), representing a monolayer to multi-layer adsorption process on mesopore and macropore walls. The gas condenses in the mesopores into bulk liquid at higher relative pressures at pressures below the saturation vapor pressure with the formation of a gas-liquid meniscus (capillary condensation). The profile of isotherms indicates a plateau with decreased adsorption at high P/P_0 . The restricting adsorption plateau at high P/P_0 suggests complete filling of mesopores and subsequent adsorption on the external surfaces.

The hysteresis loop is a feature of mesopores present in the Type IV isotherms. Several models exist to describe the phenomenon of hysteresis in adsorption isotherms [152]. Hysteresis could be predicted from non-connecting cylindrical mesopores due to variations in shapes of meniscus during capillary condensation (adsorption) and evaporation (desorption) [153].

In mesoporous materials with non-connecting cylindrical pore systems such as mesoporous silica SBA-15, such phenomena generate hysteresis profiles [152]. The pore network and pore communication effects are other mechanisms that lead to hysteresis [152], [154]- [155]. The path dependence in such interconnected pore-network systems is due to different sequences in which the molecules of the probe encounters the pores during the process of adsorption and desorption, resulting in hysteresis.

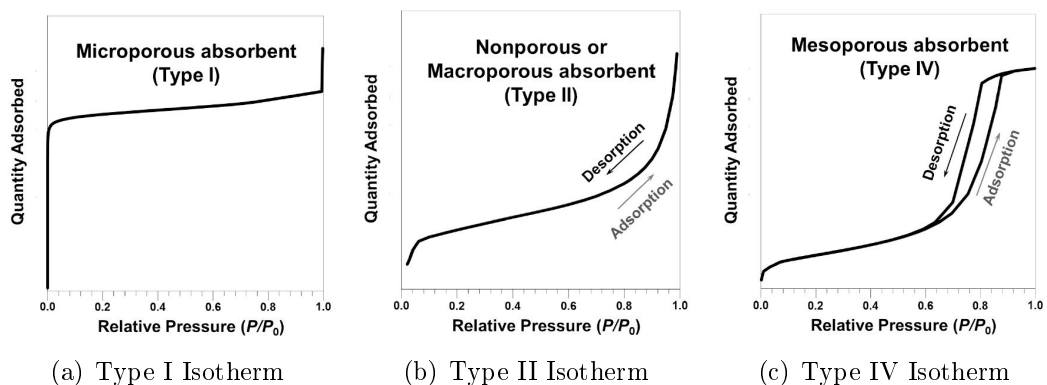

Figure 3.1: Isotherm profiles of various materials (a) purely MP (Type I) (b) MaP (Type II) and (c) purely MeP (Type IV) [150]

The variation in mesopore shapes results different characteristic for H1 to H4 hysteresis patterns (Figure 3.2). The materials which have the property of narrow distribution of cylindrical or tubular pores are exhibiting the H1 hysteresis pattern (see Figure 3.2). The H2 (Figure 3.2) types indicate a complex, interconnected pore structure with narrow pore openings. The H3 hysteresis loop (Figure 3.2) types are mostly found in materials with platy particles having slit-shaped pores. The H4 hysteresis loop (Figure 3.2) types also result from slit-shaped pores, but are associated with micropores in general.

Figure 3.2: Hysteresis shapes of adsorption isotherm usually formed in subcritical N_2 adsorption [150].

3.3 X-ray Diffraction (XRD)

An effective non-destructive technique for characterizing crystalline materials is X-ray diffraction (XRD). It includes information of structures, phases, orientations of crystals (texture), and other structural parameters, such as average of grain size of, crystallinity, strain, and crystal defects. XRD is based on constructive monochromatic X-ray interference and a crystalline sample. XRD peaks are produced by constructive interference in a sample by a monochromatic beam of X-rays dispersed from each set of lattice planes at specific angles. Consequently, in a given material, the XRD pattern is the fingerprint of periodic arrangement of atoms.

In 1912, it is also discovered that crystalline substances behave close to the spacing of planes in a crystal lattice as three-dimensional diffraction gratings for X-ray wavelengths [156]. A cathode ray tube, filtered to emit monochromatic radiation,

collimated to concentrate, and directed towards the sample, produces these X-rays. When conditions satisfy the Bragg's law, the interaction of the incident rays with the sample produces constructive interference (and a diffracted ray) as shown in Figure 3.3 and given by eqn. 3.2.

$$n\lambda = 2d\sin\theta \quad (3.2)$$

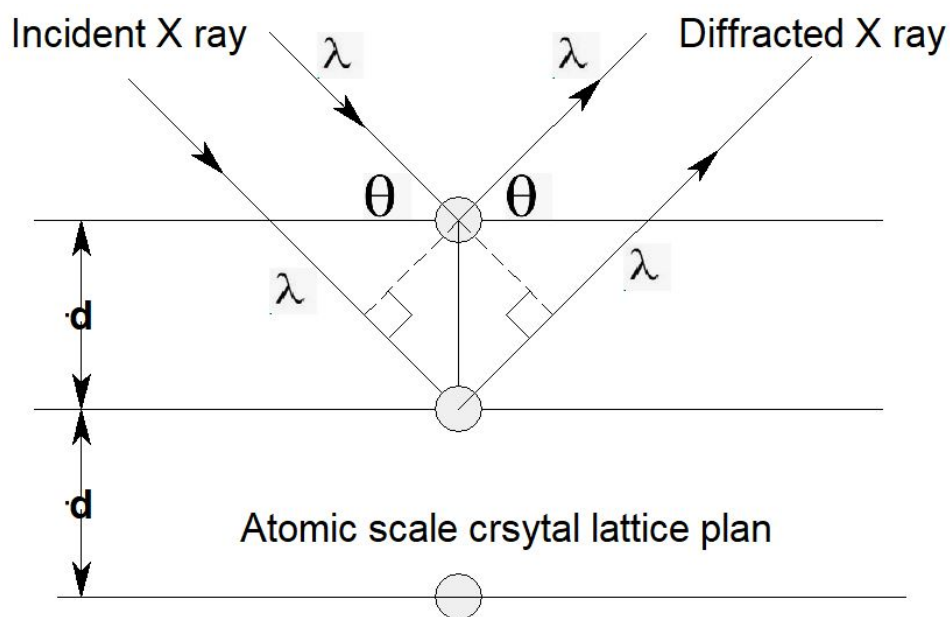

Figure 3.3: Bragg's Diffraction patterns of Incident Rays for estimating interatomic distance (d)

Where “ n ” is representing integer numbers, “ λ ” is X-ray wavelength of, “ d ” is the diffraction producing interplanary spacing, and “ θ ” is the angle of diffraction. In a crystalline sample, this law relates the wavelength of electromagnetic radiation to the diffraction angle and lattice spacing. It is also necessary to analyze the powdered material for all possible diffraction directions of the lattice by scanning the sample through the set of 2θ angles, all should be achieved.

Each sample or compound follows the uniqueness for the set of d -spacing. Therefore these diffracted peaks finally transformed d -spacings for the identification of the sample by contrasting the d -spacings to the reference patterns. Three fundamental elements are composed of X-ray diffracto-meters (see Figure 3.4): an X-ray tube, a

sample holder and an X-ray beam detector [157]. By heating a filament to produce electrons, accelerating the electrons towards a target by applying a voltage, and bombarding the target material with electrons, X-rays are produced in a cathode ray tube (see Figure 3.4(a) and Figure 3.4(b)).

(a) Schematic diagram of a diffractometer system

(b) XRD Instrument for analyzing crystal phases and crystallinity

Figure 3.4: XRD system

When the electrons have enough energy to dislodge the target materials inner shell electrons, a characteristic X-ray spectrum are formed. In order to generate monochromatic X-rays necessary for diffraction, filtering is needed by foils or crystal monochrometers. Copper, with CuK α radiation λ 1.5418 Å, is the most common target material for single-crystal diffraction. These X-rays are collimated and the sample is targeted. The intensity of the reflected X-rays is registered as the sample and detector are rotated. As Bragg's law is met by the geometry of the incident

X-rays impacting the sample, positive interference occurs and a peak of intensity appears. This X-ray signal is captured and analyzed by a detector and the signal is converted to a count rate, which is then sent to a system such as a printer or computer monitor. The X-ray diffractometer geometry is such that the sample placed at goniometer which rotates at an angle θ along the direction of the collimated X-ray beam while the X-ray detector is placed on an arm to absorb and rotate the diffracted X-rays at an angle of 2θ . Data is obtained at 2θ from 5° to 70° , angles preset in the X-ray scan, for standard powder patterns. For certain research studies in geology, environmental sciences, material science, engineering, and biology, determination of unknown solids is important. For the analysis of a wide range of materials including semiconductors, polymers, fluids, metals, plastics, minerals, thin film coatings, catalysts, pharmaceuticals, solar cells, microelectronics, and ceramics, XRD characterization technique is also globally adopted [158]. Strength and limitations of X-ray powder diffraction (XRPD).

Strengths

1. Efficiently recognize (< 20 min) the unknown sample (material)
2. Provides unambiguous mineral identification in most situations
3. Broad availability of units of XRD
4. Reasonably easy analysis of data

Limitations

1. Access to the standard inorganic compound reference file is required.
2. Material must be processed into a powder in amounts of tenth of grams
3. Detection limit for mixed materials is 2 % of the sample.
4. Indexing of patterns for nonisometric crystal systems is complex for unit cell determinations.

3.4 Scanning electron microscope (SEM)

A scanning electron microscope (SEM) is used to investigate the external morphology (texture), chemical composition, and crystalline structure and orientation of

materials making up the sample. Significant amounts of kinetic energy are carried by accelerated beam of incident electrons in a SEM. When these accelerated electrons interacted with electrons of the solid sample material, they start decelerating and lose their energies which further transform into the generation of variety of signals. These type of generated signals comprise of secondary electrons (SEs), backscattered electrons (BSEs), diffracted BSEs (used to determine crystal structures and mineral orientations), photons, visible light (cathodoluminescence -CL), and heat. For imaging samples, SEs and BSEs are commonly used. The SEs is most valuable for showing morphology and topography on samples and backscattered electrons in multiphase solid samples are most valuable for illustrating contrasts in composition. The inelastic collision between electron in the sample's atomic orbital (shell) and incident beam of electrons occurs. Electron releases energy in the form of X-rays during its transition from higher energy level (HEL) to the lower energy levels (LEL). The wavelength associated with the X-rays highly depends on the energy separation between HEL and LEL. Therefore every X-ray created is the characteristics of the element present in the sample. During the SEM analysis X-rays produced through the electron interactions do not lead to sample loss, therefore SEM is also stated as "non-destructive" sample characterization technique so that sample materials can be repeatedly analyzed.

In order to allow the sample to be imaged in a SEM, it is often necessary to prepare the sample with additional processing steps before a sample can be observed in the SEM. This method often makes the sample conductive, more stable under the electron beam and in a vacuum, or optimizes the geometry between the surface of the sample, the electron, and one (or more) of the SEM-attached detectors.

Nano-sized materials, in particular, have the problem of agglomerating or aggregating, and special treatment of the samples is required for proper imaging of these samples [159]. The type of sample preparation depends on the material type. Conductive nano sized materials such as metal oxides need little preparation, are very vacuum-stable, and under the electron beam are often stable. Sample preparation often consists of attaching them to a stub by using conductive tape for these types of samples. Due to their conductive nature, they often do not need to be coated with a metal or carbon sputter to help dissipate the accumulation of charge on the

sample surface. In order to enable good images and proper particle size analysis of nano-sized materials, sample preparation is therefore critical. In order to obtain accurate dimensions of nano-sized materials, understanding of the sample is crucial.

3.5 Materials and Methods

Ti-isopropoxide (TTIP, 97 %), ethanol (EtOH, 99.9 %) and ammonia solution (NH_3 , 28-32 wt % in water) were obtained from commercial sources and used as received. A premixture was made by simply diluting pristine TTIP with EtOH (1:6 molar ratio) inside a Teflon vessel (~ 100 mL), and after 10 minute of mild magnetic stirring ca. 70 ml of aqueous solvent (pH ~ 12 ; adjusted by NH_3 of tripled deionized water; Millipore, $18 \text{ M}\Omega_{-1}$) was carefully poured to this premixture. Within few seconds, white slurry was formed, which was kept at stirring for ca. 10 min. Then reaction was carried out at 150°C for 12 hr as shown in Figure 3.5.

Figure 3.5: Magnetic stirring of white slurry

The resulted white products were collected by centrifugation (see Figure 3.6(a)) and excessive washing with deionized water (Figure 3.6(b)). The final TiO_2 powder was obtained by drying the white product at 100°C for 4 hr (Figure 3.6(c)), and followed by the grinding (see Figure 3.6(d)).

(a) The sample of white slurry solution is centrifuged for 20 min. at 12000 rpm (b) centrifugation separated the white precipitate collected at the bottom of the vessel

(c) The white precipitate is collected and heated overnight at 100 °C (d) Final TiO₂ powder is collected after manually grinding process.

Figure 3.6: Slurry to TiO₂ powder formation

Crystalline-phase and average particle size of the processed sample (see Figure 3.6) were measured by using X-ray diffraction (XRD, PRO-MPD, Philips diffractometer) for the sample shown in Figure 3.7. BET properties were measured by N₂ adsorption-desorption at 77 K (Micromeritics ASAP-2010). Specific BET surface-area (S_{BET}), pore-volume (V_P) and pore-size (D_P) were determined from N₂ isotherms using BET and Barrett-Joyner-Halenda (BJH) methods respectively. Morphological features were examined by field-emission Scanning electron microscopy (SEM; XL30S FEG, Philips Electron Optics B.V).

Figure 3.7: Sample preparation for XRD analysis

The TiO_2 and/or Platinum (Pt) counter electrodes were prepared by screen printing the mesoscopic TiO_2 paste made with the procedure given in reference [160] and/or by depositing the hexachloro-platinic acid-based paste onto conducting FTO glass substrates (TEC-10). TiO_2 and Pt-electrode were sintered at 500°C and 400°C for ca. 30 min respectively. The redox electrolyte consisted of 0.5 M 1-butyl-3-methylimidazolium iodide, 0.05 M I_2 , 0.5 M 4-tert-butylpyridine in acetonitrile.

Figure 3.8: DSSC filled with electrolyte

The N719 dye adsorption capacity of electrodes were measured by immersing them overnight into 0.1 M NaOH solution (EtOH to water ratio 1:1) and calculating the concentration of N719-dye (extinction coefficient $\sim 1.41 \times 10^4 \text{ L}\cdot\text{mol}^{-1} \text{ cm}^{-1}$) by its light absorbance (peak at 515 nm) using UV-Vis spectroscopy (UV-2401PC, Shimadzu Corp.) The current-voltage characteristics of the assembled DSSC (see Figure 3.8 and 3.9) with Peccell solar simulator (Model: PEL-L11) were measured

under dark and 1 sun ($100 \text{ mW}\cdot\text{cm}^{-2}$, AM 1.5 G) illumination (see Figure 3.10). Using a Reference 600 Potentiostat (Gamry Instruments), electrochemical impedance spectra (EIS) were measured under 1 sun bias light at open-circuit conditions.

Figure 3.9: Assembled DSSC

Figure 3.10: J-V Characterization of assembled DSSC

3.6 Results and Discussion

Several crystalline TiO_2 powders were synthesized, however here we present one typical TiO_2 (obtained by a premixture of 1 mole of TTIP with 3.5 moles of EtOH), which is closely comparable to P-25 in its average particle size, BET surface area and pore's characteristics, and show much better parametric performance as an electrode film for a DSSC.

In the XRD pattern (Figure 3.11(a)), it is clearly seen that synthesized TiO_2 is highly crystalline with pure anatase (JCPDS Card No. 04-0477), whereas P-25 is a typical

biphasial in nature and consisted about ca. 73 % anatase (\sim 27 % rutile) as estimated by the intense 101 peaks of its anatase and rutile phases respectively [161]. The average particles' size of prepared TiO₂ is comparable with P-25 (see Table 3.1), which was estimated by XRD(101) peak using well known Scherrer's equation [34]. Both TiO₂ and P-25 powders were found mesoporous in nature (see Figure 3.11(b)) with comparable BET surface areas (see Table 3.1). The mesoscopic nature of powders is clearly indicated by their N₂ adsorption-desorption (H3-type, IV-type; BDDT classification) hysteresis loops, and such kinds of loops and BJH pore-size distributions (see inset, 3.11(b)) are typical to the nanoparticles having unordered cylindrical type pore-structures. As shown in Figure 3.11(b), N₂ capillary cohesion of as prepared TiO₂ powder occurred relatively at higher pressure indicating its larger pore features than that of a P-25 powder (see Table 3.1).

Table 3.1: Structural, textural BET features and DSSC parameters of an isotropic Degussa P-25 and rice-like anataseTiO₂

	Particle Size (nm)	S_{BET} (m^2g^{-1})	V_P (ccg^{-1})	D_P (nm)	V_{OC} (V)	J_{SC} ($mAcm^{-2}$)	FF	η (%)	Dye loading (nano $molcm^{-2}$)	f_p (Hz)
P-25	19.52	42.26	0.1211	13.05	0.788	9.45	73.2	5.45	0.569	20.58
TiO ₂	18.86	43.59	0.1952	21.94	0.845	10.78	71.3	6.49	0.571	15.52

Microscopic SEM images (see Figure 3.12(a)) show the porous nanoparticles in prepared anatase TiO₂ and biphasial P-25 powders, respectively. It is clearly noticed that P-25 nanoparticles are nearly isotropic in shape, whereas TiO₂ nanoparticles are rice-like in their shape, and such anisotropic morphological growth of particle is highly expected from ongoing hydrolysis-polycondensation reactions of a molecularly modified pristine monomeric i.e. Ti-precursor (Ti(OPr)₄) reacted with EtOH. When pristine Ti(OPr)₄ was mixed with EtOH, it is possible that some of the less electronegative OPr ligands are replaced by the more electronegative OEt ligands, hence forming a new chemical precursor Ti(OPr)_{4-x}(OEt)_x [162]- [163]. Thus difference in electronegativity of two ligands should promote an efficient decoupling between hydrolysis and polycondensation reactions [162]. Inevitably, a lesser electronegative ligand is removed quickly by OH⁻ group during hydrolysis, whereas a higher elec-

tronegative ligand is mainly replaced by OH^- group during the polycondensation process, and consequently, a decoupling between hydrolysis and condensation reactions had played a key role in formation of anisotropic shape of nanoparticles, which is concluded from Figure 3.12(b).

(a) Degussa P-25

(b) nanorice-like anatase TiO₂

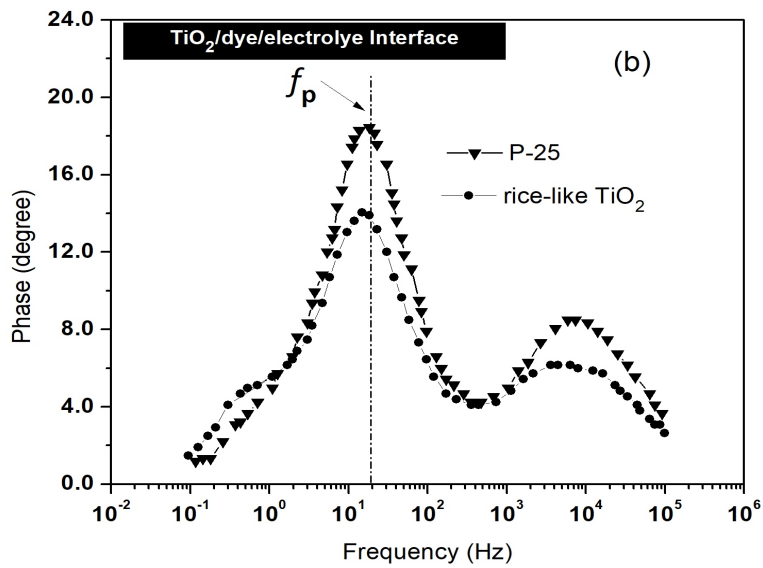

Figure 3.12: Microscopic SEM image of powder samples

Though having comparable S_{BET} and average particles' sizes (see Table 3.1) to that of a routinely exploited biphasial and isotropic P-25 powder material, yet, in any suitable potential application, nanorice-like TiO₂ powder material should demonstrate better performance due to its high crystallinity, pure phase, and more importantly a distinct anisotropic shape of its nanoparticles (see Figure 3.11 and Figure 3.12). In this view, we have tested the performance of DSSC made of a nanorice-like TiO₂ powder and a reference P-25 TiO₂ powder. It is worthwhile to mention that

DSSC assembling parameters are first optimized for spherical shape P-25 TiO₂, and such conditional parameters are also further taken as a reference for nanorice-like TiO₂ [160].

(a) Photocurrent-voltage characteristics nanorice-like anatase TiO₂ and P-25 (see Table 1)

(b) Bode plots nanorice-like anatase TiO₂ and P-25 (see Table 1)

Figure 3.13: J-V and EIS characteristics of the samples

Figure 3.13(a) shows the measured photocurrent-voltage (V-I) characteristics of cells. It is evident that under identical standard 1 sun light illumination and fabrication condition of electrode; open-circuit voltage (V_{OC}) and short-circuit photocurrent density (J_{sc}) of nanorice-like TiO₂ electrode are much improved to that

of a reference P-25 electrode. Though reference P-25 showed a relatively better fill factor (FF) due to its advantageous compact electrode film made of nearly spherical shape nanoparticles, however η of nanorice-like TiO₂ electrode was much higher (ca. 20 % enhanced) in contrast to biphasial and isotropic P-25 TiO₂ electrode.

As evident in Figure 3.13(a), higher V_{OC} of nanorice-like TiO₂ electrode could be attributed to its aforementioned pure phase and an enriched crystallinity i.e. sharp and intense XRD peaks. On the other side, along with crystallinity, enhanced J_{sc} of nanorice-like TiO₂ electrode might have initiated with factors like larger dye-adsorption amount and a better electronic conductivity. However, a very little difference was observed for adsorbed amounts of photosensitizer (N719-dye) (see Table 3.1) in the interconnected mesoporous network of both isotropic P-25 as well as anisotropic nanorice-like TiO₂, which could be understood in terms of a comparable BET surface area of the powder samples employed for electrode fabrication (see Table 3.1).

Therefore, in contrast to isotropic and biphasial P-25 electrode, it obvious that a higher J_{sc} of nanorice-like TiO₂ electrode is expedited from an enriched crystallinity, pure phase and more importantly anisotropic shape that could possess a better charge conductivity in relation with a higher life-time (τ_{el}) for dye-injected electrons into CB of mesoporous oxide film structure to the back conducting FTO glass substrate [164]. The τ_{el} was estimated from Bode-phase plots of EIS measurements of respective electrodes (see Figure 3.13(b)). The peaks of characteristic frequency ($f_p=1/2\pi\tau_{el}$) of oxide/dye/electrolyte interface for anisotropic and isotropic electrode film were situated at 15.52 Hz and 20.58 Hz respectively, thus indicated an improved τ_{el} (ca.25 %) of dye-injected charge carriers in an anisotropic rice-like anatase TiO₂ film to that of a biphasial and spherical P-25 film. Such an improved τ_{el} is obvious as any well crystalline anisotropic charge conducting geometry provides a suppressed charge recombination due to lesser defects and traps in the electron film [160].

The reported HT synthesis can be considered as convenient and readily scalable process to synthesized nanorice-like TiO₂ nano particles for the application of efficient DSSCs. Moreover scaling TiO₂ electrode thickness is another methodology to improve PV performance of the cell. Microscopic simulations are preferable approach

for investigation of generation and recombination kinetics involved in the cell in order to achieve optimized electrode thickness with minimizing the fabrication cost. In chapter 4 a detailed analyses of microscopic simulated results are reported along with experimental results to describe the mismatched performance of the cell by adopting hybrid micro macroscopic simulations.

Chapter 4

Optimizing photovoltaic efficiency of a dye-sensitized solar cell (DSSC) by a combined (modelling-simulation and experimental) study

4.1 Introduction

The photovoltaic solar energy is one of the most growing industries which is continuously focusing on new techniques to enhance the global efficiency of the cells and also relating the cell performance with environmental conditions [165]- [170]. According to literature survey mentioned in [171]- [173], there is a wide variety of photovoltaic cell technologies in the marketplace today, using different types of materials and can be categorized into three generations, depending on the raw material used and the level of commercial maturity. First generation photovoltaic systems use the technology of crystalline as well as multi crystalline silicon solar cells. Second generation photovoltaic systems are based on thin film amorphous silicon; cadmium telluride (CdTe); copper indium selenide (CIS) and copper, indium gallium diselenide (CIGS). Third generation photovoltaic systems include organic photovoltaic technologies that are still in progress or have not been widely marketed and new concepts in development. Dye sensitized solar cells (DSSC) are one of the suitable example of light harvesting devices falls in third generation photovoltaic technology. The

first dye sensitized solar cells (DSSC) were proposed in 1991 by Michael Gratzel and Brian O'Regan. These cells belong to the group of hybrid solar cells, since they are formed by organic and inorganic materials. DSSCs have been extensively studied to minimize problems related to efficiency, cost of production and environmental issues [174]- [177]. The main difference of this type of cell compared to conventional solar cells is that the functional element which is responsible for the absorption of light (the dye) is separated from the transport mechanism of the charge carriers. Thus impure raw materials and simple cell processing techniques reduces the cost of the device.

Though a DSSC consists of multiple materials, yet it is a highly realized next-generation potential photovoltaic device that has been widely investigated due to its several advantageous competencies features like working even under a dim/low light and an achievable high value of η using a straight forward, cost-effective and eco-friendly manufacturing process. To obtain a higher η , the key challenges are thus to enhance specific role of individual components of a DSSC viz. working electrode (WE), counter electrode (CE), an electrolyte; the bulk interfaces and various complex processes occurring in a DSSC [178]. Among these components, WE (charge facilitator) is the heart of a DSSC, which is a dye (photosensitizer) coated porous nanostructured thin film of TiO₂ nanoparticles or other types oxides or nano-morphologies (wire/rod/rice/tube etc.) directly or indirectly fabricated onto an optically transparent conducting oxide (FTO) substrate [179]. On light irradiation, an excited dye injects electrons into film, which diffuses or recombines until finally collected at the back of FTO substrate [180]. Since a total charge collection depends on its generation, recombination and transportation, hence a dye of suitable energy band gap with a larger optical absorbance is required. Further, losses of charge carriers needed to mimicked by optimizing kinetics role of WE, light absorptivity/energetics of dye, transportation of redox ions and charge transfer at electrode/dye/electrolyte interface [181]- [183].

Interestingly, rather than optimized DSSC performance (J-V characteristics and η) by unwieldy cost-time consuming repeated fabrication/assembling processes, one could predict an optimum η in advance using much faster, safer, inexpensive and reliable alternative methods like modelling and simulation techniques [184]- [186].

In particular, an optimum J-V characteristic and a maximum achievable η of any logical circuit based theoretical DSSC model (ideally capturing all the underlying physical processes of a real time DSSC device) could be theoretically predicted as long as necessary experimental input data of at least one pre-assembled DSSC are available for initializing the simulation process. Based on well-calibrated theoretical models, the input or output simulated results along with controlled tuneable parameters can then be used as a reference for optimizing the performance of DSSC, which help in reducing the time and the fabrication/assembling cost, as only one more post-assembling process is required to achieve an optimum DSSC device.

Here in this chapter, the assembling and J-V characteristics of a sandwiched type DSSC assembled by a WE ($L \sim 3.0 \mu\text{m}$) made from commercially available and nearly spherical shape TiO_2 nanoparticles (Degussa, P-25), an iodide /triiodide redox liquid electrolyte and photosensitizing dye N719 is reported. The measured J-V curve of assembled DSSC was generated by simulating a theoretical DSSC by TCMM-simulation (drift-diffusion of collective charge carriers) and SDMM-simulation in MATLAB (single p-n junction diode; Lambert W-function technique) [187]. The correlated and calibrated input model parameters (microscopic model: L, porosity, recombination kinetics, light absorbance of a N719 dye etc.; macroscopic model: shunt resistance $\sim R_S$, series resistance $\sim R_{SH}$ etc.) were further utilized in controlled simulation to achieve a maximum L corresponds to an optimum η of a DSSC device. The validation of correlated simulation and experimental output parameters (V_{OC} - open-circuit voltage; J_{SC} - short-circuit photocurrent density; FF- fill factor; η ; P_{MAX} - maximum power density; V_{OPT} - voltage at P_{MAX} ; J_{OPT} - current density at P_{MAX}) of DSSC are discussed together with pro and cons of input parameters of theoretical models.

4.2 Electrode fabrication, DSSC assembling and J-V measurements

Electrode fabrication and DSSC assembling were done according to the procedure as given in reference [160]. A homogenous paste was made by mixing P-25 powder, α -terpineol and ethyl-cellulose. This paste was screen printed on commercially

available F-doped SnO₂ (FTO; TEC 8) glass substrate. The TiO₂ electrode (active area ~ 0.25 cm²; L ~ 3.0 μ m) was soaked in a 0.5 mM solution of N719 dye (acetonitrile and tert-butanol 1:1 volume ratio) for 24 hours. As received N719 dye from Solaronix has been used (no purification was done). The counter electrode was Pt-coated FTO glass substrate. Dye coated electrode were rinsed in anhydrous ethanol, dried in N₂ flow and a sandwich type DSSC has been assembled by stacking and sealing electrodes (spacer of 60 μ m thickness; thermoplastic Surlyn frame) filled with a redox couple electrolyte (0.5 M 1-butyl-3-methylimidazolium iodide, 0.05 M I₂, 0.5 M 4-tert-butylpyridine (TBP) in acetonitrile).

Electrical contacts were made by silver (Ag) soldering and Copper (Cu) wires. J-V characteristics of an assembled DSSC were measured under 1 sun (100 mW/cm², AM 1.5G) illumination with Peccell solar simulator (Model: PEL-L11). The measured output parameters (V_{OC} ; J_{SC} ; FF; η ; P_{MAX} ; V_{OPT} ; J_{OPT}) of a DSSC are listed in Table-4.2.

4.3 Theoretical modelling and simulation of a DSSC structure

With the current assembling and fabrication processes of a DSSC structure, the impact of TiO₂ (L) on J-V characteristics curve is predicted and studied by a TCMM-simulation under a static 1 sun light illumination. Further, it is assumed that a total charge neutrality is maintained in modelling and simulation work. The results of microscopic and macroscopic simulations are compared with the results of a real time experimental work.

One-dimensional microscopic modelling-simulation is performed in multiscale *tiber*-CAD software in which a set of drift-diffusion equations, continuity equations (eqn.4.1-4.4), and Poisson's relation are used for facilitation of charge carriers (electrons, holes and redox ions) describing the kinetics involved in the operation of DSSC and further used to understand the kinetics involved in DSSC (see Figure. 4.1) [188].

$$\Delta.(\mu_e n_e \Delta.\phi_e) = (G - R) \quad (4.1)$$

$$\Delta.(\mu_{I^-}n_{I^-}\Delta.\phi_{I^-}) = \frac{3}{2}(G - R) \quad (4.2)$$

$$\Delta.(\mu_{I_3^-}n_{I_3^-}\Delta.\phi_{I_3^-}) = (G - R) \quad (4.3)$$

$$\Delta.(\mu_c n_c \Delta.\phi_c) = 0 \quad (4.4)$$

Where $\mu_{I_3^-}$, μ_{I^-} , μ_e and μ_c are the mobility of I_3^- , I^- , electrons and cation; $n_{I_3^-}$, n_{I^-} , n_e and n_c are the concentrations of I_3^- , I^- , electrons and cation. G and R represent the generation and recombination rate of carriers as given by eqn. (4.10,4.12). The purpose to consider cation is to maintain charge neutrality of the device and there will be no current contribution due to cation. We assume valid Einstein's relation (eqn.4.5) between mobility (μ) and diffusion coefficient (D), where k is Boltzmann constant, T is temperature and e is charge on electron.

$$D = \frac{kT}{e}\mu \quad (4.5)$$

The concentration of the various species in a cell is governed by Maxwell–Boltzmann distribution and given by eqn. (4.6-4.9) under equilibrium condition.

$$n_e = N_{CB} \exp(-kT(e\varphi - e\phi - E_c)) = \bar{n}_e \exp(-kTe(\varphi - \phi)) \quad (4.6)$$

$$n_{I^-} = \bar{n}_{I^-} \exp(-kTe(\varphi - \phi_{I^-})) \quad (4.7)$$

$$n_{I_3^-} = \bar{n}_{I_3^-} \exp(-kTe(\varphi - \phi_{I_3^-})) \quad (4.8)$$

$$n_c = \bar{n}_c \exp(-kTe(\varphi - \phi_c)) \quad (4.9)$$

where E_c is the conduction band (CB) edge in TiO_2 , φ is the electrical potential, N_{CB} is the effective density of states in TiO_2 conduction band and ϕ is the electrochemical potential. The barred quantities in chemical equation refer to the equilibrium concentrations at no sunlight condition. The generation term (G) related to the flux of photons which absorbed by the dye coated active TiO_2 regions. The generation rate (G) is evaluated by considering the dye absorption spectrum (N719) in the present study of DSSC [189]- [191] and defined by the eqn. (4.10).

$$G(x) = \int_{400 \text{ nm}}^{800 \text{ nm}} (\alpha(\lambda)\psi(\lambda)e^{-\alpha(\lambda)x})dx \quad (4.10)$$

where $\psi(\lambda)$ is the spectral power flux simulating a standard solar illumination on at 1 sun. Parameter $\alpha(\lambda)$ is the absorption coefficient of the dye chemisorbed on the TiO_2 . Above 800 nm, the absorption of the dye is quite small.

The recombination depends on the loss mechanisms at the electrolyte/ TiO_2 interface [192]. The principal losses occur when an electron from the CB of TiO_2 recombines with the triiodide. In the case of a DSSC, the charge transfers occur at the interfaces of the electrolyte with the Pt contact and with the TiO_2 . The total reaction of I_3^-/I^- redox electrolyte is a two-electron reaction (eqn. 4.11) [193].

The recombination rate, R is governed by the eqn. (4.12) and mainly affected by recombination constant rate k_e (for recombination path r_3), concentration of electrolytes, electron density and β is the exponent for the electron density.

$$R = k_e \left(n_e^\beta \sqrt{\frac{n_{I_3^-}}{n_{I^-}}} + \bar{n}_e^\beta \sqrt{\frac{\bar{n}_{I_3^-}}{\bar{n}_{I^-}^3} \bar{n}_{I^-}} \right) \quad (4.12)$$

Beside drift-diffusion equations, the Poisson's equation (eqn. 4.13) is considered for the internal potential drop in the cell with dye generation rate G and k_3 (dye regeneration rate constant) for oxidized dye molecule concentration, N_D^+ (eqn. 4.14).

$$-\varepsilon \Delta \varphi = e(n_c - n_{I_3^-} - n_{I^-} - N_D^+ - n_e + \bar{n}_e) \quad (4.13)$$

$$N_D^+ = \frac{G}{k_3} \quad (4.14)$$

Redox energy level of the electrolyte is expressed by the Nernst equation and given by eqn. (4.15). The I_3^-/I^- boundary conditions at the cathode are related to a Butler–Volmer (BV) eqn. (4.16-4.18) and controlled by the concentration of redox species. $j_{cathode}^0$ is the exchange current density, which describes the charge transfer between Pt and I_3^- at equilibrium; Δn_{I^-} and $\Delta n_{I_3^-}$ are the diffusion over potential. All the barred terms represents respective quantities in dark condition. E_0^{redox} is the standard redox potential; where L is the length of the electrode and represents the current density.

$$E_{redox} = E_{redox}^0 + \frac{kT}{2} \ln \left(\frac{\bar{n}_{I^-}{}^3 n_{I_3^-}}{n_{I^-}^3 \bar{n}_{I_3^-}} \right) \quad (4.15)$$

$$j = j_{cathode}^0 \left(\exp \frac{\beta e}{kT} \Delta n_{I_3^-} - \exp \frac{-(1-\beta)e}{kT} \Delta n_{I^-} \right) \quad (4.16)$$

$$\Delta n_{I_3^-} = \frac{kT}{e\beta} \ln \left(\frac{n_{I_3^-}(L)}{\bar{n}_{I_3^-}} \right) \quad (4.17)$$

$$\Delta n_{I^-} = \frac{kT}{e(1-\beta)} \ln \left(\frac{n_{I^-}(L)}{\bar{n}_{I^-}} \right) \quad (4.18)$$

The BV equation fixes the total current density that must split between I_3^- and I^- species. Beside the boundary conditions (eqn. 4.19-4.21), simulations also included two other constraints for these two ionic species (eqn. 22-24).

$$\int_0^d (n_{I^-}(x) + 3n_{I_3^-}(x)) dx = (\bar{n}_{I^-} + \bar{n}_{I_3^-})L \quad (4.19)$$

$$\int_0^d n_c(x) dx = \bar{n}_c d \quad (4.20)$$

$$\Delta \cdot (\mu_{I^-} n_{I^-} \Delta \cdot \phi_{I^-}) = \frac{1}{2e} j \quad (4.21)$$

$$\Delta \cdot (\mu_{I_3^-} n_{I_3^-} \Delta \cdot \phi_{I_3^-}) = -\frac{3}{2e} j \quad (4.22)$$

All the above equations (eqn. 4.1-4.22) are implemented in a finite-element solver *tiberCAD* by considering equivalent 1 D structure of DSSC as shown in Figure. 4.2, that produced the several DSSC results viz. I-V characteristic curves, density profiles, total recombination etc. [194].

In this microscopic model (see Figure 4.1), all injected electrons are considered from the excited state of dye only, and not from TiO_2 band gap excitation. The trapping and de-trapping of dye-injected electrons is neglected in an electrode irrespective to

its L value [195]. This model consisted of two regions: 1) mesoporous electrode of TiO₂ nanoparticles surrounded by a liquid electrolyte; and 2) a liquid electrolyte in contact with a counter-electrode (covered by a thin Pt-layer) [196]- [198]. Optical losses caused by a liquid electrolyte are not included and it is assumed that each absorbed photon injected one electron into conduction band of TiO₂. Moreover, it should be noted that only one dominant electron recombination loss mechanism ($r_3 \rightarrow$ between TiO₂ and electrolyte; see Figure 4.1) is considered in the present microscopic model [199].

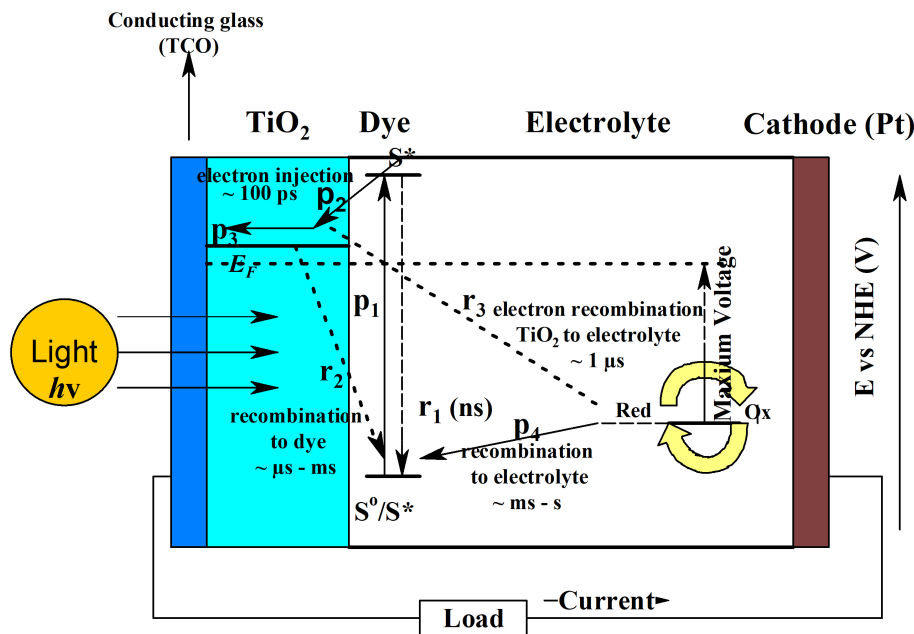

Figure 4.1: Illustration showing the working principle and the components of a DSSC structure, where dash arrows represented the various paths (time-scales) for electron loss.

Macroscopic modelling-simulations are performed in MATLAB tool. A non-ideal single-diode model is used (see Figure 4.3; eqn. 4.23) for keeping the simplicity and an accurate representation of simulation results (minimum error in a nonlinear J-V curve) of a DSSC structure. This model consist of: 1) a photocurrent source (J_L ; depends upon light irradiance) connected in parallel with a non-ideal diode (n , ideality factor; J_0 , saturated dark current density) 2) a series resistance (R_s ; capturing total resistive losses within cell) and 3) a shunt resistances (R_{sh} ; representing losses due to an increased conductivity at junction/edges of cell) [200]. Based on Schokley

theory of a p-n junction diode, the J-V characteristics curve of such a non-ideal single-diode model [201]- [202] is mathematically expressed by eqn. 4.23, where V_T is the thermal voltage. Due to implicit transcendental form of this eqn. 4.23, it is quite tedious task to extract individual diode parameters by a common least-square curve fitting method, therefore this cumbersome extraction process was made simple by changing the implicit form into an explicit form with the application of a Lambert W-function (see eqns. 4.24 and 4.25) [203].

Figure 4.2: 1-D microscopic DSSC model used in *tiberCAD* software (only significant loss mechanism r_3 of Figure. 4.1 is used in simulation)

Figure 4.3: 1-D macroscopic electrical DSSC model used in MATLAB simulation

Precautions were taken during simulations, as the accuracy of extracted input parameters (J_L , J_0 , n , R_s and J_{sh}) depends on the choice of their initial surmise, which may tend to lead a non-convergence equation. Moreover, as the number of fitting parameters increases, the non-linear fitting method loses their ability to give the accurate results.

4.4 Correlations between Simulation and Experimental Results

By considering the pre assembled DSSC based on a WE (N719 adsorbed nanoparticles based TiO₂ electrode, active area $\sim 0.25 \text{ cm}^2$, $L \sim 3.0 \mu\text{m}$), a liquid redox couple electrolyte I₃⁻/I⁻ and counter Pt-electrode, the J V characteristics obtained experimentally (see Figure. 4.4) is utilized to calibrate the simulation parameters of the *tiberCAD* software by performing TCMM simulations for 1-D microscopic DSSC device model (see fig.4.2) under standard 1 sun light illumination conditions. The calibrated parameters are noted down (Table 4.2) after achieving close fit between the experimental and simulated results (see Figure. 4.4 and Table 4.1).

$$J = J_L - J_o \left(\exp \frac{V + JR_{sh}}{nV_T} - 1 \right) - \frac{V + JR_s}{R_{sh}} \quad (4.23)$$

$$J = \frac{R_{sh}(J_L + J_o) - V}{R_s + R_{sh}} - \frac{nV_T}{R_s} W(Q) \quad (4.24)$$

$$Q = \frac{J_o R_{sh} R_s}{nV_T (R_s + R_{sh})} \left(\frac{(R_{sh}(R_s J_L + R_s J_o + V))}{nV_T (R_s + R_{sh})} \right) \quad (4.25)$$

Table 4.1: Experimentally measured results* and simulated** DSSC PV performance parameters

J _{SC} mAcm ⁻²	V _{OC} (V)	V _{OPT} (V)	J _{OPT} mAcm ⁻²	P _{MAX} mWcm ⁻²	FF (%)	η (%)
5.95**	0.812**	0.71**	7.74**	5.495**	84.2**	4.07**
5.94*	0825*	0.66*	5.2*	3.432*	72.5*	3.55*

Along with the experimentally measured results, the simulated output DSSC parameters are listed in Table 4.1. A discrepancy in a FF (and η) among experimental and simulated J-V characteristics curves is clearly observed in Figure 4.4, and such mismatch in FF is more pronounced in a non-linear region of J-V curves. This mismatch can be understood in terms of limitations imposed in model software, particularly neglecting the resistance contribution of a FTO substrate in a WE is one of the key limitations of TCMM (*tiberCAD*) simulations. Despite of an overestimation in FF, however it is clear from Table 4.1 that at-least V_{OC} and J_{SC} obtained through real time experiments and theoretical microscopic model-simulations matches well

for a TiO_2 electrode ($L \sim 3.0 \mu\text{m}$) and provides motivation to carry out further simulations for various electrode thicknesses.

Figure 4.4: TCMM-simulation and experimental J-V characteristic curves of a DSSC at $L \sim 3.0 \mu\text{m}$

Table 4.2: Calibrated input parameters obtained by microscopic modelling-simulations of 1D DSSC model at $L = 3 \mu\text{m}$ thick TiO_2 electrode (see Figure 4.4)

S.No	Input parameters (for TCMM simulations)	Calibrated values
1	Electron relaxation rate, k_e	$0.07 \times 10^4 \text{ s}^{-1}$
2	Electron mobility, μ_e	$0.02 \text{ cm}^2/\text{V s}$
3	Iodide diffusion constant, D_{I^-}	$8.5 \times 10^{-6} \text{ cm}^2/\text{s}$
4	Triiodide diffusion constant, $D_{I_3^-}$	$8.5 \times 10^{-6} \text{ cm}^2/\text{s}$
5	Initial conc. of iodide, $[I^-]$	0.45 M
6	Initial conc. of triiodide, $[I_3^-]$	0.45 M
7	Recombination exponent, β	0.75
8	Cell porosity, P	0.5
9	Cell area, A	0.25 cm^2

By adapting all the calibrated input parameters of Table 4.2 as references, TCMM-simulation is repeated for various L ($6.0 \rightarrow 18.0 \mu\text{m}$) of a WE, so that more meaningful (qualitative and quantitative) insights could be gain about the L dependency of output parameters.

Figure 4.5: TCMM-simulation J-V characteristic curves of a DSSC at L ($3 \rightarrow 18 \mu\text{m}$)

4.5 Results and Discussion

By considering results of TCCM simulation (see Figure 4.4; Table 4.3), three more DSSC devices for different L (6.0, 9.0 and 12.0 μm) of a WE are fabricated/assembled and characterized (see section 4.2). Experimental values together with simulated output parameters of such devices are listed in Table 4.3, and for quick and simple observations, their L dependency behaviors are plotted in Figures 4.6-4.9 and Figure 4.11.

From Table 4.3 or Figures 4.6-4.9, a systematic WE (L) dependency of various DSSC output parameters (V_{OC} , J_{SC} , FF, η) is clearly noticeable i.e. an increasing J_{SC} ($\sim 5.95 \rightarrow 9.4 \text{ mAcm}^{-2}$) with an increasing thickness ($\sim 3 \rightarrow 12 \mu\text{m}$) and then a decreasing J_{SC} for other higher values of thicknesses (above 12 μm). Additionally, η of a DSSC WE follows the similar tendency (see Figure 4.6), while exhibiting its optimum ($\eta \sim 6.23 \%$) for a particular WE (L $\sim 12.0 \mu\text{m}$). Despite of having a much higher η in simulated J-V characteristics plots, above results suggested that η is indeed essentially determined by J_{SC} , and its trend is fully verified by the experimental measurements (see Figures 4.6-4.9; Table 4.3) [204]. As the light transmitted into the depth of a WE, a gradual decrease in power density of light takes place and

excessive electron density becomes lower, therefore results in decrease in V_{OC} (0.812 \rightarrow 0.78 V) in an initial range of L, 3.0 \rightarrow 9.0 μm [205]- [207]. For further increments in L (12.0 \rightarrow 18.0 μm), V_{OC} shows insignificant variation [208] and settled at close to 0.78 V. Moreover, comparison of the simulated parameters with experimental measurements, the significant variation could be easily interpreted in terms of typical L dependent behaviour of J_{SC} caused by two competing simultaneous and contradictory kinetics occurring a WE i.e. generation and recombination of charge carriers in an assembled DSSC structure (See Figure 4.1) [209].

Figure 4.6: TCMM-simulation and experimental output parameter; J_{SC} of a DSSCs obtained under 1 sun illumination for various L of a TiO_2 electrode

Figure 4.7: TCMM-simulation and experimental output parameter; V_{OC} of a DSSCs obtained under 1 sun illumination for various L of a TiO_2 electrode

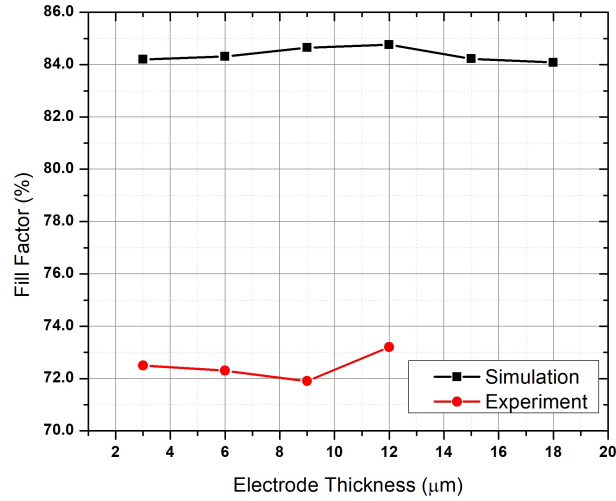

Figure 4.8: TCMM-simulation and experimental output parameter; FF of a DSSCs obtained under 1 sun illumination for various L of a TiO₂ electrode

Figure 4.9: TCMM-simulation and experimental output parameter; η of a DSSCs obtained under 1 sun illumination for various L of a TiO₂ electrode

The incomplete dye covering together with a lack of light intensity deep into a thicker WE lead a gradual decrease in its J_{SC} . Besides this, a thicker WE film offers more bulk resistance at the interconnected grain boundaries of TiO₂ nanoparticles [210]- [211].

Based upon the above discussions i.e. a subtle balance between two opposite charge transport kinetics (see Figure 4.1) and adopting the calibrated input model parameters of a reference WE (see Figure 4.1; Table 4.2) in microscopic modelling-simulation studies, $L \sim 12 \mu\text{m}$ (see Figures 4.6-4.9; Table 4.3 and 4.4; $FF \sim 84.76\%$; $V_{OC} \sim 0.782 \text{ V}$; $J_{SC} \sim 9.4 \text{ mAcm}^{-2}$; $\eta \sim 6.23\%$; $J_L \sim 9.49 \text{ mA}^{-2}$ and $R_S \sim$

29.37 m Ω cm² ; see Table 4.3 and 4.4) was estimated as optimum L of a WE, as fully supported by the aligned parallel experimental measurements. Note that R_S or R_{SH} values (see Table 4.4 of an individual WE are estimated from a slope of J-V curve using SDMM simulations, while neglecting the contribution (resistance in R_S) of a FTO in J-V curves.

Table 4.3: Experimentally measured results* and simulated** DSSC PV performance parameters

Parameter	L= 3 μ m	L= 6 μ m	L= 9 μ m	L= 12 μ m	L= 15 μ m	L= 18 μ m
J _{SC} mAcm ⁻²	5.95** 5.94*	8.28** 8.70*	9.15** 9.2*	9.4** 9.45*	8.93** --	8.72** --
V _{OC} (V)	0.812** 0.825*	0.79** 0.82*	0.78** 0.80*	0.782** 0.79*	0.78** --	0.78** --
V _{OPT} (V)	0.71** 0.66*	0.695** 0.647*	0.685** 0.63*	0.69** 0.616*	0.685** --	0.68** --
J _{OPT} mAcm ⁻²	7.74** 5.2*	7.943** 7.97*	8.82** 8.39*	9.03** 8.8*	8.57** --	8.41** --
P _{MAX} mWcm ⁻²	5.495** 3.432*	5.52** 5.15*	6.04** 5.29*	6.23** 5.42*	5.87** --	5.718** --
FF (%)	84.2** 72.5*	84.31** 72.30*	84.65** 71.9*	84.76** 73.2*	84.22** --	84.08** --
η (%)	4.07** 3.55*	5.52** 5.15*	6.06** 5.3*	6.23** 5.46*	5.87** --	5.71** --

Figure 4.6-4.9 and Table 4.4 clearly depict that for a particular WE (L~12 μ m), the high percentage values of FF (~16%) and η (~14%) obtained in TCMM-simulations as compared to their experimental values, are consequences of assumptions made by model simulation software (*tiberCAD*), particularly as FTO series resistance could not be taken into simulations. Therefore, the effects of L on J-V curves are further investigated in MATLAB using SDMM-simulation with an application of a Lambert function (see Figure 4.3; eqn. (4.23-4.25)). For SDMM simulations, previously as resulted TCMM-simulations and experimental J-V curves of various L are taken as inputs, and a better fitting is achieved by applying a least square fitting method within a minimum permissible error range (SSE = 8.5x10⁻⁷ to 5x10⁻⁶, R square = 0.9965 to 0.9974, RMSE = 1x⁻⁴ to 1x10⁻³).

The extracted macroscopic model input parameters (J_L, J₀, n, R_s and R_{sh}) for different values of L (TCMM simulated J-V characteristics; see Figure 4.5) are reported and compared in Table 4.4. For all L of a WE, Table 4.4 depicts a much lower

(ca. $\sim 10^3$ fold) magnitude of R_s resulted in TCMM-simulation than to its values extracted from experimental J-V curves.

Table 4.4: Experimentally measured results* and simulated** DSSC PV performance parameters

L	R_s ($m\Omega cm^2$)	R_{sh} ($K\Omega cm^2$)	(n)	J_o	J_L
3 μm	106.6**	66.95**	1.389**	1.024**	6.087**
	11.32×10^3 *	63.2*	1.432*	1.88*	5.82*
6 μm	67.4*	92.42*	1.35*	1.4*	8.48*
9 μm	37.62*	97.06*	1.292*	0.7*	9.38*
12 μm	29.37**	973**	1.365**	2.55**	9.49**
	7.07×10^3 *	82.5*	1.39*	3.4*	9.04*
15 μm	40.11*	151*	1.263*	0.48*	9.04*
18 μm	80.42*	117*	1.365*	3.142*	8.93*

The drastically lowered values of R_s closely reflected a much higher FF and η for all L of a WE as reflected in all TCMM-simulations. To overcome the limitation of TCMM-simulation, the FTO resistance is considered through the combination of TCMM-simulation and SDMM-simulation, and this combined approach is referred as hybrid micro-macroscopic model simulation (HDMM-simulation).

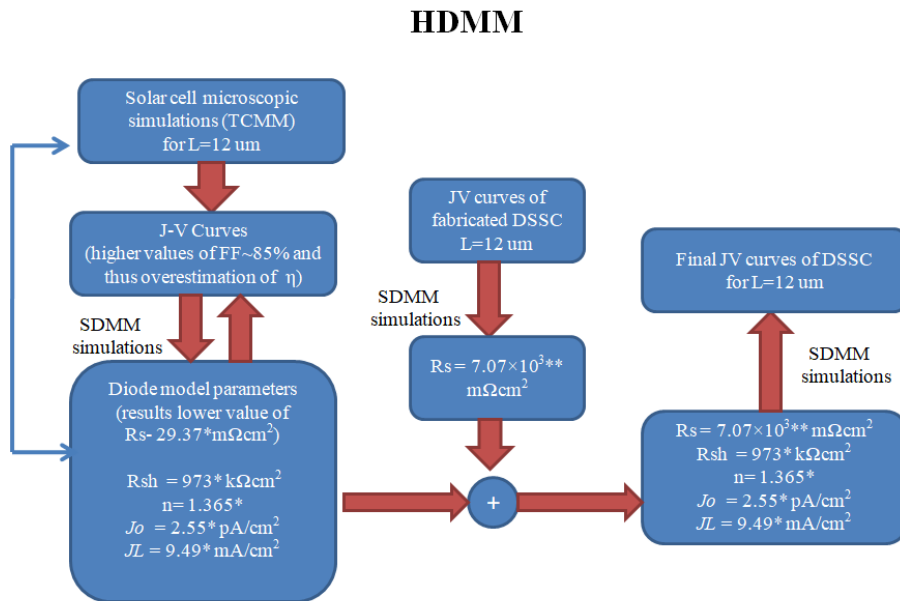

Figure 4.10: HDMM-simulation model

Figure 4.11: Experimental and TCMM-simulation J-V characteristics curves obtained under 1 sun light illumination for an optimized DSSC ($L=12 \mu\text{m}$) along with HDMM simulation curve by considering FTO resistance ($7.07 \times 10^3 \text{ m}\Omega\text{cm}^2$)

Figure 4.11 shows the comparison of J-V curves among an experimental, a TCMM-simulation and a HDMM-simulation for a DSSC producing a maximum η for a particular L ($\text{ca} \sim 12 \mu\text{m}$) of a WE. It is clear that a very close fitting of performance parameters of the solar cell (see Table 4.5) is obtained between J-V curves obtained by a real time experiment and a HDMM-simulation. Moreover, a dramatic influence a FTO resistance in R_s (unaccounted in microscopic model and a counted in macroscopic model) and curve fitting is clearly noticed. The last column in Table 4.5 shows the percentage error in HDMM-simulation with their real time measured experimental values. The maximum percentage error in η and FF is found to be $\eta \sim 0.06 \%$ and 0.52% respectively, between measured experimental values and HDMM simulations.

Additionally, the variation of photocurrent density (J_L) with L is entirely consistent with the dependency of R_s on L value (see Figure 4.12). The R_s is determined to be a minimum for a particular TiO_2 electrode ($L \sim 12 \mu\text{m}$), and this could be explained by considering the two simultaneously competing contradictory mechanisms occurring in an electrode i.e. generation and recombination of charge carriers in an assembled DSSC structure [212]- [213].

Table 4.5: Comparison among TCMM-simulation, Experimental and HDMM-simulation parameters for an optimized DSSC structure consisting a TiO_2 electrode (thickness $L=12 \mu\text{m}$, 0.25 cm^2).

Parameter	Microscopic simulations TCMM	Experimental results (Exp)	Hybrid Model simulations	% error Exp - TCMM	% error Exp-Hybrid model
$R_S \text{ m}\Omega\text{cm}^2$	29	7.07×10^3	7.07×10^3	99.58	0

Figure 4.12: Thickness dependent output parameter (R_S , J_L) of a DSSC TiO_2 electrodes obtained by SDMM simulations performed in MATLAB

Increasing the thickness of WE increase the dye absorbance in the TiO_2 porous voids thus enhance the light absorbance in the photoanode (WE) and further increases the density of photo- generated carriers. Hence photo current density increases but at the same instant of time, series resistance of the electrode also tends to increase in order to affect the cell performance.

It can be understood from the above results shows that scaling the electrode thickness shows improvement in PV performance of the DSSC. However, the performance of the cell is directly depends on the mechanism of the charge transfer processes oc-

curing inside the cell. Thus it is essential to explore the electron transport properties impacting net charge transportation and accumulation at the various interfaces and bulk regions present in the cell. In chapter 5, electrochemical impedance spectroscopy (EIS) analysis is employed for analyzing these mechanisms describing the relationship between the cell's performance and its architecture.

Chapter 5

Analysis of charge transport

properties of dye sensitized solar cell (DSSC) with TiO_2 working electrode by employing electrochemical impedance spectroscopy (EIS)

5.1 Introduction

Electrochemical impedance spectroscopy (EIS) is widely preferred technique to elucidate the charge transfer (CT) and transport properties of the DSSCs [214]- [227]. It is a steady state approach that measures the current response as a function of frequency to the application of an AC voltage.

This chapter reports the Electrochemical impedance spectroscopy (EIS) characteristics of a sandwiched type DSSCs assembled by a WE ($L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$) made from commercially available and nearly spherical shape TiO_2 nanoparticles (Degussa, P-25), an I_3^-/I^- redox liquid electrolyte and photosensitizing dye N719 (as discussed in chapter 4). EIS is employed on DSSCs in order to insight on many significant processes taking place inside the cell of in order to investigate the charge transport, transfer, and accumulation in DSSC such as: (i) electron percolation inside TiO_2 film through diffusion and I_3^-/I^- diffusion in the electrolyte solution; (ii) recombination

($e-I_3^-$) at TiO_2 /electrolyte (T-E) interface (iii) regeneration of I^- at Pt/electrolyte (P-E) interface; and (iv) capacitive elements inside cell including interfaces, CB, and across the TiO_2 network [215], [218]- [222]. The Nyquist diagram usually involves three semicircles attributed to the Nernst diffusion inside the electrolyte, the electron transfer at the oxide/electrolyte interface, and the redox reaction at the platinum counter electrode in the order of increasing frequency. The characterized EIS spectrums (nyquist and bode plot) are further utilized to investigate the charge transfer and transport properties of the DSSC fabricated for electrode thicknesses (L) from $3 \mu m$ - $12 \mu m$ (discussed in chapter 4) by curve fitting method using EIS spectrum analyzer software. EIS spectrum were measured using a reference 600 potentiostat (Gamry Instruments) under 1 sun in the open-circuit condition.

5.2 Fundamentals of EIS

The net impedance over a wide range of frequency ($\omega = 1/2\pi f$) across the circuit element of the electrical network is computed by measuring the ac current on applying ac input voltage across the circuit element. The eqn. (5.1) is used to calculate the resulting impedance $Z(\omega)$ of the system [214]- [215], [217] provided that $I(\omega, t)$, is sufficiently small to be linear in relation to $V(\omega, t)$ or vice versa. Depending on the numerous CT process taking place inside the DSSC, $V(\omega, t)$ and $I(\omega, t)$ may differ amplitude and phase at a range of certain frequencies (f) resulting in the impedance for the corresponding CT process. Any electrical network is said to be powered with dc current when the frequency (f) of the applied voltage source is close to 0 Hz, and the network's impedance is evaluated by its DC resistance (R_{dc}), i.e. zero phase impedance is given by eqn. (5.2) [215], [223]:

$$Z(\omega) = \frac{V(\omega, t)}{I(\omega, t)} \quad (5.1)$$

$$Z(0) = \frac{V(0, t)}{I(0, t)} = R_{dc} \quad (5.2)$$

For an small signal AC input voltage described by $V(\omega, t) = V_0 \cdot e^{-j\omega t}$, generates AC current which is expressed by $I(\omega, t) = I_0 \cdot e^{-j\omega(t-\theta)}$. It is clearly shown that there is a phase difference (θ) appearing between voltage and current. Eqn.(5.1) can be

written as eqn. (5.3).

$$Z(j\omega) = \frac{V_0}{I_0} e^{-j\omega} \quad (5.3)$$

Again, eqn. (5.3) can be also expressed in terms of magnitude of net impedance ($|Z|$) and given by eqn. (5.4)

$$Z(j\omega) = |Z| e^{-j\omega} \quad (5.4)$$

After applying Euler's theorem eqn. (5.4) can be expressed by eqn. (5.5)

$$Z(j\omega) = |Z|(\cos\theta + j\sin\theta) \quad (5.5)$$

The total impedance of the electrical network is expressed by eqn. (5.6) [13,16]

$$Z(\omega) = Z_{Re} + jZ_{Im} \quad (5.6)$$

where $Z_{Re} = |Z|. \cos\theta$ and $Z_{Im} = |Z|. \sin\theta$ are representing real and the imaginary impedances of $Z(j\omega)$ respectively. Impedance's magnitude ($|Z|$) and θ are expressed as eqn. (5.7) and eqn. (5.8) respectively.

$$|Z| = \sqrt{Z_{Re}^2 + Z_{Im}^2} \quad (5.7)$$

$$\theta = \tan^{-1} \left(\frac{Z_{Im}}{Z_{Re}} \right) \quad (5.8)$$

There are various ways to display the computed EIS data to analyze CT characteristics of the DSSC. One of the plots termed as Nyquist plot where is plotted against Z_{Re} in the complex plane. Plotting of other parameters from EIS curves; $\log|Z|$ and θ as a function of $\log f$ is known as Bode plot. Moreover plotting Z_{Im} against $\log f$ also helps to investigate the charge recombination properties inside the cell [214]- [217].

5.3 EIS Spectra of DSSCs

The process involved in CT and electron loss mechanism involved in DSSC is shown in Figure 5.1 where path (1) represents the electron injection process. The charge injection efficiency depends on the energy gap between LUMO level (lowest unoccu-

piated molecular orbital) of dye and CB of TiO_2 and capability of the dye molecules anchored on the surface of TiO_2 nanoparticles. These properties regulates the electron injection time at dye/ TiO_2 interface. After injection process, electron transport towards FTO glass by diffusion process through path (2).

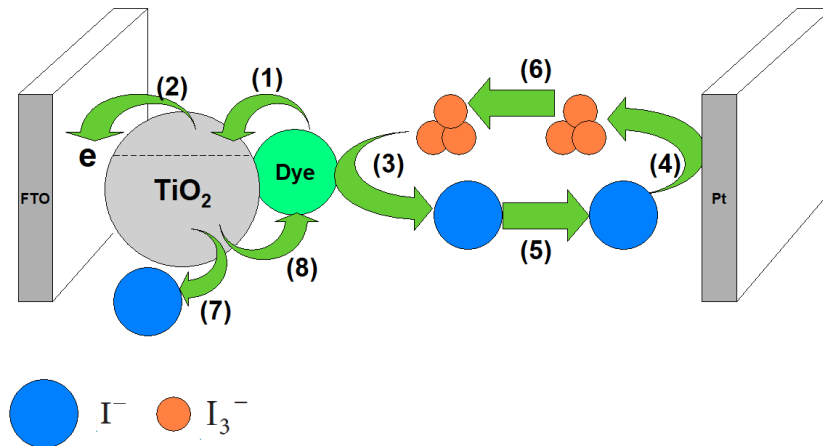

Figure 5.1: Representation of CT kinetics(1) e-injection process, (2) e-diffusion inside TiO_2 film, (3) dye regeneration (4) regeneration kinetics of I_3^-/I^- (5) diffusion of I_3^- in electrolyte solution (6) diffusion of I^- , (7)recombination of TiO_2 CB electrons with I_3^- and(8)e- S^+ recombinations

The ability of electron diffuses inside the network of TiO_2 nano particles is governed by the diffusion resistance offered by TiO_2 network which further depends on the electron recombination process taking place at the surface of TiO_2 (T-E interface) or inside the bulk of TiO_2 . It can be assumed that electrolytes ions (I_3^-/I^-) present uniformly in the solution. The triiodide redox electrolyte diffuses towards the oxidized dye molecules and regenerates them through path (3) and gets self oxidized into iodide ion. This dye reduction process enhances the concentration gradient of iodide ions which further tends to diffuse the iodides towards the Pt coated FTO glass so that it get reduced to form triiodide ions (path (4)) to maintain the dye regeneration kinetics in the cell. It can be easily understood that better diffusion property for path (6) and path (5) of the electrolyte ions are required in electrolyte solution to maintain the redox reactions in the cell. So in terms of electrical quantity, it can be also understood that electrolyte solution should provide lower diffusion resistance for the electrolyte ions for faster redox reactions in order to enhance regeneration of redox mediator (I_3^-/I^-). The oxidized dye molecules may also get

reduced by capturing electron from the TiO_2 network through path (8) and this path can be considered as the recombination path. However, the dominant electron loss mechanism can be given by the electron capturing by triiodide ions through path (7) which is further influenced by the charge recombination kinetics involved at the T-E interface. Charge recombination kinetics further decides the charge recombination across the T-E interface i.e. higher the CT resistance at T-E interface lower is the electron recombination through path (7) or vice versa. From the above discussion it can be illustrated that performance of the DSSC fabricated with various electrode thicknesses ($L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$) can be also expressed in terms of impedances in the bulk and at the interface regions present in the cell.

Employing EIS determines the current response as a function of frequency by applying ac input voltage $V(\omega, t)$ resulting Nyquist plots usually involves three semicircles (I-III) corresponds to different charge transport process at the interface and inside the components of the DSSC. A DSSC is usually composed of a photosensitive (N719, N3, LEG4) dye adsorbed on FTO glass substrate coated with mesoporous film of nanocrystalline TiO_2 which acts as working electrode WE, an I_3^-/I^- derived redox couple, and an Pt-FTO glass substrate acting as CE. The photo electrochemical processes, including electronic and ionic processes (diffusion and recombination) taking place in the DSSC has been widely investigated by EIS.

A well frequency distribution of several time constants for the different CT paths (paths 1-8) gives rise to three distinct arcs as shown in Figure. 5.2(a) or representing three distinct peaks in plotted in Bode plot (see Figure. 5.2(a)) of EIS of a DSSC. The theoretical and experimental approach [224]- [228] has been used to assign these semicircles in the EIS spectrum to the corresponding CT processes. The three semicircles are clearly depicted from the Figure. 5.2(a). As traversing towards $\omega = 0$ rad/s, the semicircle - I (near $\omega \sim \infty$ rad/s) representing the CT processes taking place at Pt/electrolyte interface with a characteristic frequency ω_{CE} , the second (II) or middle semicircle corresponds to the electron diffusion in the TiO_2 film and electron back reaction with I_3^- at the TiO_2 /electrolyte interface at characteristic frequency ω_d and ω_k respectively, and the third (III) semicircle plotted near low frequency region corresponds to the diffusion of I_3^- ions in the electrolyte solution with a characteristic frequency ω_D .

(a) Nyquist Plot of DSSC observed from EIS spectrum representing three semicircles (I-III)

(b) Bode Plot of DSSC observed from EIS spectrum

Figure 5.2: Example of EIS pattern for DSSC

All characteristic frequencies except ω_d are shown in the Bode plot (Figure. 5.2(b)), ω_d is appearing as a break point as high frequency limit of semicircle II of Nyquist plot (Figure. 5.2(a)) at certain steady-states but not in the Figure.5.2(b). The physical parameters representing the electron transport inside the DSSC can be determined by curve fitting of experimentally measured EIS spectra to an equivalent circuit comprises of resistances and capacitances [225]- [229]. The most preferable equivalent circuit of the complete DSSCs is a represented by transmission line model as shown in Figure 5.3, where r_{ct} represents the CT resistance related to recombina-

tion at $\text{TiO}_2/\text{I}_3^-$ interface; chemical capacitance of the TiO_2 film is given by c_u ; r_t is representing electron transport (diffusion) resistance in TiO_2 film; Z_d corresponds to Warburg element showing the Nernst diffusion of I_3^- in electrolyte; R_{Pt} and C_{Pt} are the CT resistance and double-layer capacitance (DLC) at the Pt CE; R_{ct} and C_{TCO} are the CT resistance and the corresponding DLC at exposed TCO/electrolyte interface; R_{CO} and C_{CO} are the resistance and the capacitance at TCO/ TiO_2 contact; R_{STCO} is the sheet resistance of FTO glass. It is considered as L is the thickness of the mesoscopic TiO_2 film [218].

Figure 5.3: Transmission line model: Equivalent circuit representing complete DDSSC

The most significant processes are listed below with the equivalent impedance which is individually responsible for shaping the EIS of complete DSSCs.

5.3.1 Ohmic Series Resistance

For DSSC, sheet resistance of electrode substrate (TCO glass) and the resistance of the electrolyte solution may be considered as a major contributor to the ohmic series resistance (R_{OS}) in DSSCs. For (R_{OS}), the impedance (Z_{OS}) is given by eqn. (5.9).

$$Z_{OS} = R_{OS} \quad (5.9)$$

5.3.2 Charge transfer (CT) at the CE

R_{Pt} at electrolyte/CE interface (see Figure. 5.3) is related to the redox reaction involving I^- and I_3^- in order to proceed the reaction; $e(\text{Pt}) + 1/2.\text{I}_3^- = 3/2.\text{I}^-$.

R_{Pt} is expressed by Buttlar-Volmer equation with exchange current density (j_0) and given by eqn. (5.10) [234].

$$R_{Pt} = \frac{RT}{mFj_0} \quad (5.10)$$

where R ($8.31 \text{ Jmol}^{-1} \text{ K}^{-1}$) is the ideal gas constant, F ($96485.33 \text{ Cmol}^{-1}$) is Faraday constant, T is the temperature (K), and m is number of electrons participated in the reaction. CT process at the counter electrode (CE) can be modeled by considering a parallel R-C circuit (see Figure. 5.3) with the equivalent impedance (Z_{Pt}) which can be expressed by given eqn. (5.11).

$$Z_{Pt} = \frac{R_{Pt}}{1 + j^{n_{CE}} R_{Pt} Q_{Pt}} \quad (5.11)$$

Therefore, ω_{CE} can be determined by eqn. (5.12) and Q_{Pt} , equivalent capacitance (C_{Pt}) can be determined by eqn. (5.13).

$$\omega_{CE} = \frac{1}{R_{Pt} Q_{Pt}^{1/n_{Pt}}} \quad (5.12)$$

$$C_{Pt} = Q_{Pt}^{1/n_{Pt}} R_{Pt}^{1/n_{Pt}-1} \quad (5.13)$$

5.3.3 Electron Diffusion and Recombination at the WE

In DSSCs, electron transport in the TiO_2 is coupled with electron loss mechanism at the TiO_2 /electrolyte interface, typically referred as a recombination. Several study groups have thoroughly researched the diffusion and recombination impedances experienced by electrons at the WE of DSSCs [224], [226], [230]- [231]. The equivalent impedances for diffusion and recombination process as given by Z_{WE} (see eqn.(5.16)) which is significantly appears in the semicircle II of EIS spectra of DSSC as shown in Figure. 5.2(a). The characteristic frequencies, ω_k and ω_d are clearly depicted in Figure. 5.2(a)) and given by eqn. (5.14-5.15). In practice, CPE is also considered as a distributed capacitance in order to account the non ideality present in the diffusion-recombination processes in DSSC. For this case, ω_d for Z_{WE} can be also given by eqn.(5.14) [232]- [233].

$$\omega_k = \frac{1}{R_k Q_k^{1/n_k}} \quad (5.14)$$

Similarly, ω_d can be written as eqn. (5.15) [232]- [233]

$$\omega_d = \frac{1}{R_d Q_k^{1/n_k}} \quad (5.15)$$

$$Z_{WE} = \sqrt{\frac{R_d R_k}{1 + (j\omega/\omega_k)^{n_k}}} \text{Coth} \sqrt{\left(\frac{\omega_k}{\omega_d}\right) \left\{1 + \left(\frac{j\omega}{\omega_d}\right)^{n_k}\right\}} \quad (5.16)$$

where R_d is the electron transport or diffusion resistance, R_k is the electron transfer resistance related to e^-/I_3^- recombination, and Q_k and n_k are the CPE (constant phase element,) prefactor and index, respectively. Additionally, C_u is termed as chemical capacitance formed across the TiO_2 film permeated with electrolytes and given by eqn. (5.17).

$$C_u = Q_k^{1/n_k} R_k^{1/n_k - 1} \quad (5.17)$$

5.3.4 Diffusion of I_3^- in the Electrolyte Solution

The solution of redox couple is maintained such that, the $[I^-] \gg [I_3^-]$, so it can be assumed that, mainly I_3^- contributes to the diffusion impedance (in electrolyte solution) that appearing at near $\omega \sim 0$ rad/s region (see Figure. 5.6). The diffusion impedance of I_3^- ions is modeled by transmission line of finite-length (FL) with short-circuits terminus and the corresponding FL Warburg impedance (Z_{DI}) [225]- [227] is given by eqn. (5.18).

$$Z_{DI} = R_{DI} \sqrt{\frac{D_I/\delta^2}{j\omega}} \tanh \sqrt{\frac{j\omega}{D_I/\delta^2}} \quad (5.18)$$

where Z_{DI} is the diffusion impedance experienced by I_3^- , D_I is the diffusion coefficient of I_3^- , and δ representing diffusion length of I_3^- in electrolyte solution, which is considered as half of electrolyte spacer [226]. Eqn. (5.18) is also illustrating an impedance of FL diffusion with absorbing boundary condition provided that $\omega_D = D_I/\delta^2$. The frequency maxima ($\omega_{max} \sim$ peak frequency) are related to ω_D as $\omega_{max} = 2.5\omega_D$.

5.3.5 Representation of EIS Spectra of Complete DSSCs

According to Figure. 5.2(a) and Figure. 5.2(b), the impedances Z_{OS} , Z_{WE} , Z_{DI} , and Z_{Pt} are capable to define a complete equivalent electrical circuit representing DSSCs [218]- [227]. Thus, net impedance across the anode and cathode of the DSSC. (Z_{DSSC}) can be expressed as by summation of eqn. (5.9), (5.11), (5.16), and (5.18) and given by eqn. (5.19) and shown in Figure. 5.4.

Figure 5.4: Schematic representing Net impedance Z_{DSSC} across anode and cathode

$$Z_{DSSC} = Z_{OS} + Z_{Pt} + Z_{WE} + Z_{DI} \quad (5.19)$$

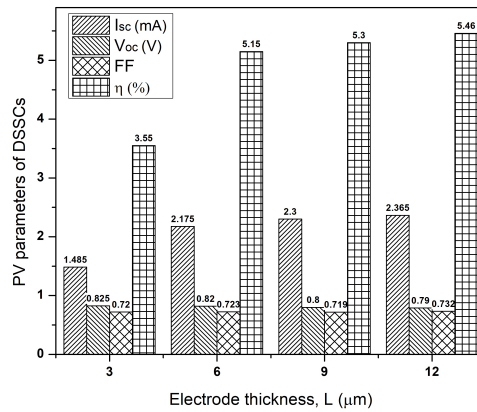

5.4 Results and Discussion

Along with PV curves of the DSSCs, the power generated curves are also mentioned in Figure. 5.5(a)-Figure. 5.5(c). It can be clearly depicted that the maximum power (P_{max}) generated by the DSSCs upon light illumination increases from 3.35 mW \rightarrow 5.46 mW for $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$ (see Figure. 5.5(b)). As the L increases ($3 \mu\text{m} \rightarrow 12 \mu\text{m}$), the dye loading also enhances which further enhances the dye absorbance, hence increases the light absorption. Assuming TiO_2 is not of absorbing any light spectrum. Dye is the only photosensitive material responsible for absorbing the photons. The light absorbing capability of dye coated WE directly related to its L is given by eqn. (5.20), where A is absorbance of dye, C is dye concentration (M), ε is molar extinction coefficient of dye ($\text{M}^{-1}\text{cm}^{-1}$).

$$A = C\varepsilon L \quad (5.20)$$

Surface area of the TiO_2 film increases with electrode thickness L of WE results more anchoring sites for N719 dye molecules to get adsorbed. As clearly seen from

eqn. (5.20) absorbance increases with L hence it increases the number of photons absorbed by photosensitive dye which further increases charge generations to enhance I_{SC} (see Figure. 5.5(c)). Increasing the L , improves the η of DSSCs from 3.55 % \rightarrow 5.45 %, FF do not show significant variations and V_{OC} reduces from 0.825 V \rightarrow 0.79 V (see Figure. 5.5(c)). The overall improvement in the η of the cell is mainly driven by the number of photons absorbed by the WE. In addition to analysis of light absorbing capability of WE, it is also required to investigate the CT and transport properties of DSSCs with various electrode thicknesses (L).

(c) PV parameters of fabricated DSSCs of $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$

Figure 5.5: PV curves and performance of the DSSCs

The EIS characteristics for the fabricated DSSC ($L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$) are measured and shown in Figure.5.6 representing Nyquist plot and it is clearly observed that measured bode plot from EIS spectra have three semicircles for every DSSC fabricated for $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$. Measured semicircles in the EIS spectrum were allocated to the corresponding processes of CT taking place in the DSSC.

As traversing from $\omega \sim \infty$ rad/s \rightarrow 0 rad/s (see Figure. 5.6) Z_{Pt} is describing the first (I) semicircle which is representing CT processes at the P-E interfaces with ω_{CE} , Z_{WE} is describing the second (II) is representing to the electron diffusion in the TiO₂ film coupled with electron back reaction with I₃⁻ at the T E interface, and Z_{DI} describing third (III) semicircle ($\sim\omega_D$) at near of $\omega \sim 0$ rad/s region corresponds to the diffusion of I₃⁻. It is also observed that the real part of impedance of DSSC (Z_{Re}) at $\omega = 0$ rad/s is also shifting towards the lower values of Z_{Re} for increasing L (3 μ m \rightarrow 12 μ m) and it can be illustrated that series dc ohmic resistance is also decreasing on increasing L. It can be easily depicted from the Figure. 5.6 that the height and width of the second semicircle defined for Z_{WE} is also decreases for increasing L (3 μ m \rightarrow 12 μ m). Additionally the peak of Z_{Im} is shifting towards the low frequencies (see Figure. 5.6, Figure. 5.10). The eqn. (5.16) can be rearranged for assumption $n_k = 1$, $\omega \ll \omega_d$ rad/s and given by eqn. (5.21) and further separately expressed for high frequencies ($\omega \gg \omega_k$ rad/s) and low frequency ($\omega \ll \omega_k$ rad/s) regions and given by eqn. (5.22) and eqn.(5.23) respectively [221]- [223] and difference between eqn.(5.23) and eqn. (5.22) relates the width ($\sim R_k$) of the second semicircle defined by (Z_{WE}).

$$Z_{WE} = \frac{R_d}{3} + \frac{R_k}{1 + \frac{j\omega}{\omega_k}} \quad (5.21)$$

$$Z_{WE}(\omega \sim \infty \text{rad/s}) = \frac{R_d}{3} \quad (5.22)$$

$$Z_{WE}(\omega \sim 0 \text{rad/s}) = \frac{R_d}{3} + R_k \quad (5.23)$$

From the above equation it can be illustrated that width of the second semicircle represents the resistance R_k as CT resistance related to electron recombination with I₃⁻ ions at the T-E interface. Figure. 5.6 clearly depicts that R_k is decreases for increasing; hence CT resistance decreases for L (3 μ m \rightarrow 12 μ m). Increasing L (3 μ m \rightarrow 12 μ m) increases the dye loading capacity of the TiO₂ electrodes which further tends to increase electron-hole pair generation upon light illumination hence increases I_{SC} (mA) as shown in Figure. 5.5(c). Figure. 5.6 also illustrates that the impedance point $Z_{WE}(\omega \gg \omega_k) = R_d/3$ and impedance point $Z_{WE}(\omega \ll \omega_k) = R_d/3 + R_k$ which is shifting towards the lower values of Z_{Re} that clearly indicates that electron

diffusion resistance inside the TiO_2 film also varies for increasing L .

Figure 5.6: Nyquist Plots of fabricated DSSCs of $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$

To investigate and validate the charge transport properties in terms of parameters quoted in eqns. (5.9-5.18), it is required to fit the simulated EIS curves (Nyquist plot) based on theoretically modeled equations (eqn. 5.9, 5.11, 5.16, 5.18) with experimentally measured the EIS curves for fabricated DSSC of L ($3 \mu\text{m} \rightarrow 12 \mu\text{m}$) in order to analyze impact of electrode thickness on charge transport properties of DSSC. Fitting of simulated EIS curves are done by EIS spectrum analyzer software by incorporating LevMarq and NM Simp algorithm. In this software, Z_{OS} is simply modeled as ohmic resistance R_1 , Z_{Pt} is representing a double layer capacitance at electrolyte/CE interface which is modeled as CPE. CPE resembles with the capacitance but impedance angle is not 90° , so the admittance of CPE is given by $Y_{CPE} = (j\omega)^{n_{CPE}} Q_{Pt}$. The equivalent capacitance of CPE is given by $C_{Pt} = Q_{Pt}^{1/n_{Pt}} R_{Pt}^{1/n_{Pt}-1}$. Now Z_{Pt} is modeled as CPE in parallel with $R_2 = R_{Pt}$ in the software. The Z_{WE} is modeled as U (user defined) element (see eqn. 5.24) in the software by mentioning real and imaginary part and given by eqn.(5.25-5.26).

$$Z_{Uelement} = \frac{R_d}{3} + \frac{\omega_k^2 R_k}{\omega^2 + \omega_k^2} - j \frac{\omega \omega_k R_k}{\omega^2 + \omega_k^2} \quad (5.24)$$

$$Z_{Re} = \frac{R_d}{3} + \frac{\omega_k^2 R_k}{\omega^2 + \omega_k^2} \quad (5.25)$$

$$Z_{Imj} = \frac{\omega \omega_k R_k}{\omega^2 + \omega_k^2} \quad (5.26)$$

The impedance for I_3^- in the electrolyte solution (Z_{DI}) is modeled by equivalent impedance element (Z_{Ws1}) called Warburg short terminus given by eqn. (5.27), where W_{sr} ($\Omega\text{cm}^2 \text{ s}^{-0.5}$) and W_{sc} ($\text{s}^{-0.5}$) are known as the Warburg coefficients.

$$Z_{Ws1} = \frac{W_{sr}}{\sqrt{\omega}} (1-j) \tanh(W_{sc} \sqrt{j\omega}) = W_{sr} W_{sc} \sqrt{2} \sqrt{\frac{1}{W_{sc}^2 j\omega}} \tanh(\sqrt{W_{sc}^2 j\omega}) \quad (5.27)$$

Comparing eqn. (5.27) and eqn. ((5.18), it is observed that the diffusion resistance for I_3^- in the electrolyte solution, (R_{DI}) can be expressed in terms of Warburg coefficients and given by eqn. (5.28), where $W_{sc} = \delta/D_I^{0.5}$.

$$R_{DI} = W_{sr} W_{sc} \sqrt{2} \quad (5.28)$$

The Figure. 5.7 shows the equivalent circuit representing the various impedances inside the DSSC and employed for fitting experimentally measured EIS curves for L ($3 \mu\text{m} \rightarrow 12 \mu\text{m}$). to obtain the charge transport properties illustrating the kinetics involved in the solar cell.

Figure 5.7: Equivalent model of DSSC representing electrochemical impedances responsible for charge transport properties involved in CT kinetics

Figure 5.8 and Table. 5.1 shows the simulation window of EIS spectrum analyzer and upper limits and lower limits for the fitting parameters which are representing charge transport parameters, where $R1(\Omega\text{cm}^2) = R_{OS}$, $R2(\Omega\text{cm}^2) = R_{Pt}$, $P1(\mu\text{Fcm}^2) = Q_{Pt}$, $n1 = n_{Pt}$, $UP1(\Omega\text{cm}^2) = R_d$, $UP2(\Omega\text{cm}^2) = R_k$, and $UP3(\text{rad/s}) = \omega_k$ respectively.

Figure 5.8: Shows the simulation window of EIS spectrum analyzer

On the basis of above description, the following fitted EIS curves are achieved as shown in Figure 5.9 for DSSC fabricated for $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$.

Figure 5.9: Fitted Nyquist plots (EIS curves) using EIS spectrum analyzer software for DSSC $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$.

Table 5.1: Limits for parameters of equivalent circuit (EIS) model)

Limits	R1	R2	P1	n1	W_{sr1}	W_{sc1}	UP1	UP2	UP3
Upper	15	10	0.5	1	10	0.2	10	100	150
Lower	2	2	1×10^{-5}	0.05	0.1	0.05	0.005	1	1

Table 5.2: Fitted parameters (eqn. 5.9-5.28) achieved from EIS spectrum analyzer for DSSCs $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$

L(μm)	R1	R2	P1	n1	W_{sr1}	W_{sc1}	UP1	UP2	UP3
3	3.125	1.73	15.3	0.757	1.625	0.48	0.01	8	175.64
6	3.2	1.82	38.3	0.67	1.06	0.59	0.18	4.9	110.25
9	2.92	1.89	37.5	0.67	1.49	0.53	0.275	4.25	95.61
12	3.0	1.48	43.3	0.65	1.36	0.62	0.564	4.05	80.67

Simulations are carried out to achieve Nyquist Plots (see Figure 5.8) of an equivalent circuit (see Figure. 5.7) representing electrochemical impedances occurring inside DDSCs. Table 5.2 listed the fitted parameters for EIS spectrum analyzer for DSSCs achieved by fitting of simulated Nyquist plots with experimentally measured Nyquist Plots (EIS curves) for DSSC DSSC for $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$. On the basis of listed parameters in Table 5.2, Table 5.3 listed the charge transport properties computed from eqn. eqn. 5.9-5.28.

Table 5.3: Charge transport properties (eqn. 5.9-5.28) of DSSC ($L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$) achieved by fitting of measured EIS curves by EIS spectrum analyze for DSSC

L(μm)	R_{OS}	R_{Pt}	Q_{Pt}	n1	R_{DI}	R_d	R_k	f_k
3	3.125	1.73	15.3	0.757	1.11	0.01	8	27.45
6	3.2	1.82	38.3	0.67	0.88	0.18	4.9	17.54
9	2.92	1.89	37.5	0.67	1.16	0.275	4.25	15.21
12	3.0	1.48	43.3	0.65	1.19	0.564	4.05	12.83

From Table 5.3 and Figure. 5.6, it can be illustrating a consistency between the width of the Nyquist plots ($L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$) and the electron transport resistance, R_k . Squeezing of the width of the Nyquist plots is clearly interprets the decrease in R_k from $8 \Omega\text{cm}^2 \rightarrow 4.05 \Omega\text{cm}^2$ for $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$ respectively. For spacer of $60 \mu\text{m}$, the computed values of diffusion constant (D_I) for I_3^- electrolyte by relation, $W_{sc} = \delta/D_I^{0.5}$ are $1.56 \times 10^{-4} \text{cm}^2\text{s}^{-1}$, $1.04 \times 10^{-4} \text{cm}^2\text{s}^{-1}$, $1.28 \times 10^{-4} \text{cm}^2\text{s}^{-1}$

and $0.95 \times 10^{-4} \text{cm}^2 \text{s}^{-1}$ for $L = 3 \mu\text{m}$, $6 \mu\text{m}$, $9 \mu\text{m}$ and $18 \mu\text{m}$ respectively. In addition to D_I , the CT resistance (R_{Pt}) across P-E interface does not show significant variation for L .

Characteristic frequency f_k also shifted towards low frequencies for increasing L (see Table 5.3) and improves the electron life time (τ_e) in the TiO_2 electrode (see Table 5.4). The net series ohmic resistance (R_S) of the DSSC can be also expressed in terms of charge transport parameters observed from EIS curve fitting and given by eqn. (5.29) and listed in Table 5.4. It is observed that the R_s (see eqn. 5.29) of the DSSC is also decreases with L such that highest value of R_S ($14.5 \Omega\text{cm}^2$) is noticed for $L = 3 \mu\text{m}$ and insignificant variations for remaining L . It can be easily interpreted as R_k at T-E interface reduces for increasing the L .

$$R_S = R_{OS} + R_{Pt} + R_{DI} + R_k + \frac{R_d}{3} \quad (5.29)$$

Table 5.4: Series resistance (R_S), electron life time (τ_e) and characteristic frequency (f_k) estimation through EIS curve fitting method for DSSC $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$

Parameters	$L = 3 \mu\text{m}$	$L = 6 \mu\text{m}$	$L = 9 \mu\text{m}$	$L = 12 \mu\text{m}$
$R_s(\Omega\text{cm}^2)$	14.5	11.04	11.62	10.06
$\tau_e(\text{ms})$	5.8	9.07	10.4	12.4
f_k	27.45	17.54	15.21	12.83
$\omega_d(\times 10^{-4})$	21.9	0.477	0.235	0.092
$L_n(\mu\text{m})$	2400	163	139	86

From the Figure. 5.10 It is clearly depicted that the peak of the imaginary impedance (Z_{imj}) shifting towards the lower frequencies for increasing the electrode thicknesses ($L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$) i.e. characteristic frequency f_k decreases from $27.45 \text{ Hz} \rightarrow 12.83 \text{ Hz}$ for increasing $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$. Additionally is also noticed that peak of the imaginary impedance ($-Z_{imj}$) also decreases from $4.1 \Omega\text{cm}^2 \rightarrow 2.23 \Omega\text{cm}^2$ for increasing the electrode thicknesses ($L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$) respectively. The electron life time is given by $\tau_e(1/2\pi f_k)$; calculated as 5.7 ms , 9.07 ms , 10.4 ms , 12.4 ms for DSSC fabricated for $L = 3 \mu\text{m}$, $6 \mu\text{m}$, $9 \mu\text{m}$ and $12 \mu\text{m}$ respectively. It is clearly investigated that electron life time get improved for increasing L ($3 \mu\text{m} \rightarrow 12 \mu\text{m}$). Improvement in electron life time can be also considered as another factor for increases in I_{SC} and overall η of the DSSC. Moreover it is clearly observed that for

each L as listed in Table. 5.3, the relation $R_k \gg R_d$ validates the presence of strong diffusion of electrons in TiO_2 electrode which can be illustrated as high conductivity of the electrode.

Figure 5.10: Plots of DSSC, $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$ representing the characteristic frequency f_k and τ_e .

In addition to $R_k \gg R_d$, the consistency with $\omega_d \gg \omega_k$ is also reported (see Table. 5.4 and Table. 5.4) as given by eqn. (5.30). Despite of existing finite R_k in DSSC causing recombination at T-E interface, the lower electron diffusion resistance (R_d) in TiO_2 WE is continuously transporting the injected electrons efficiently at the front TCO glass substrate. It can be easily understood that diffusion and recombination processes occurs simultaneously at WE however the relation $R_k / R_d \gg 1$ (see Table 5.3) is seems to be existed for $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$ to maintain the electron transport effectively through diffusion process. The computed values of effective diffusion length (L_n) of the electrons is listed in Table 5.4 given by eqn.(5.31) are much higher than each electrode thickness (L).

$$\frac{R_k}{R_d} = \frac{\omega_d}{\omega_k} \quad (5.30)$$

$$L_n = L \frac{R_k}{R_d} \quad (5.31)$$

The maximum V_{OC} that can be achieved is given by eqn. (5.32), where E_F is defined as fermi level of TiO_2 semiconductor and E_{redox} is defined as redox potential of the redox couple which depends on the electrolyte concentration resulting impact on V_{OC} (see eqn. 5.33).

$$V_{OC} = E_F + E_{redox} \quad (5.32)$$

$$E_{redox} = E_o + \frac{RT}{nF} \ln \frac{[I_3^-]}{[I^-]^3} \quad (5.33)$$

Figure. 5.5(c) clearly depicts that V_{OC} is decreases from 0.825 V \rightarrow 0.79 V for $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$. Here E_{redox} remains fixed due to fix I_3^-/I^- concentration, so shifting E_F downwards resulting lowering of V_{OC} (see eqn. 5.32). Moreover the energy difference between LUMO and HOMO levels of dye is also remain constant, hence it can be illustrated that lowering of E_F resulting efficient electron injection (Dye \rightarrow TiO₂). The improved life time can be attributed to reduced recombination of photo-generated electrons between the T-E interface.

The recombination depends on the loss mechanisms at the electrolyte/ TiO_2 interface. The principal losses occur when an electron from the CB of TiO_2 recombines with the triiodide. Losing electron tends TiO_2 to p type semiconductor, shifts the E_F downwards, and reduces open circuit voltage.

Chapter 6

Conclusion and Future Scope of the Work

6.1 Conclusion

Crystalline nanorice-like anatase TiO_2 powder can be well synthesized in a one-pot HT reaction simply by taking advantage of the electronegativity difference of the attached ligands. The average particle size and exposed BET surface area of the resulting nanorice-like TiO_2 powder are quite similar to those of a commercially available benchmark (reference) TiO_2 powder (Degussa P25). The reported HT synthesis process is very convenient, easy and readily scalable. Moreover the synthesized nanorice-like TiO_2 material showed good performance in a DSSC. Thus, such nanorice-like TiO_2 could be potentially adapted as a reference material in numerous applications, whenever and wherever possible.

Thickness of a working electrode (WE) affected the performance of its assembled DSSC structure. TCMM-simulation depicts that as thickness increase, short-circuit photocurrent density (J_{sc}) firstly increases ($\sim 5.95 \rightarrow 9.4 \text{ mAcm}^{-2}$) for electrode thickness from $3 \mu\text{m}$ to $12 \mu\text{m}$, and achieve a maximum (9.4 mAcm^{-2}) at $12 \mu\text{m}$ and then decreases ($9.4 \text{ mAcm}^{-2} - 8.72 \text{ mAcm}^{-2}$) for electrode thickness from $12 \mu\text{m}$ to $18 \mu\text{m}$. The maximum J_{sc} (9.4 mAcm^{-2}) is obtained for a $12 \mu\text{m}$ thick WE. The similar trend is observed for maximum power points and DSSC efficiency. The optimum value of value of electrode thickness is found to be consistent with the experimental results and a single diode model as well (SDMM). In general, the

simulated TCMM results do not match well with the experimental observations, particularly a fill factor (error 15.8 %) and efficiency (error 14.02 %), and probably one of the possible major reasons is an unaccounted FTO resistance in simulation (tiberCAD) software. To account the FTO resistance, HDMM-simulation is carried out where the extracted value of R_s from experimental J-V curve is used along with other SDMM parameters extracted from TCMM (as input). The obtained simulated DSSC results are in close agreement with the experimental results with the tolerable permissible error for $FF \sim 0.52$ % and for $\eta \sim 0.055$ %.

Henceforth, clever, feasible and well understandable modelling-simulation study just requiring initial experimental data of a preassembled DSSC device could become highly economical and beneficial to make an optimized DSSC through only and only one more additional post assembling process. It have been recently proved that the performance of the dye solar cell can be improved by developing new semiconductor absorber, counter electrodes and electro-hole transporter layers which should offer new opportunities in light harvesting areas. Photoelectrode is the critical component which determines the light harvesting capability of DSSC device. Hence by finding the high yielding routes for synthesis of various morphologies for TiO_2 nanoparticles such as nano rods and rice like structures with suitable band gap and, the efficiency of DSSC device will be able to match with the efficiency of other type of solid state devices.

Thickness of a working electrode (WE) affected the performance of its assembled DSSC structure. Surface area of the TiO_2 film increases with electrode thickness L of WE results more anchoring sites for N719 dye molecules to get adsorbed. Therefore more photons get absorbed by the DSSCs leads to more charge generation upon light illumination and may lead to enhance the η of DSSC. However the analysis of diffusion process and recombination kinetics of charge carriers is also further required for investigation of charge transport properties affecting the performance of the cell. Simulating and fitting of EIS curves achieved from theoretical modeled equations using EIS spectrum analyzer software can be considered as a promising approach for parameters extraction for realization of charge transport properties of the DSSCs. The findings of improved life time (τ_e) of electrons is attributed to reduced recombination rate (ω_k , $175.64 \text{ rads}^{-1} \rightarrow 80.67 \text{ rads}^{-1}$) of photo-generated

electrons across the TiO_2 /electrolyte interface hence increases the CT. More over EIS fitted results also investigated that effective electron diffusion length L_n ($2400 \mu\text{m} \rightarrow 86 \mu\text{m}$) in WE is much greater than electrode thickness L ($3 \mu\text{m} \rightarrow 12 \mu\text{m}$) which further satisfies $R_k \gg R_d$ required in order to maintain strong diffusion inside the WE. The combined effect of improved dye loading and τ_e ($5.8 \text{ ms} \rightarrow 12.4 \text{ ms}$) are considered as responsible factors to increase the η of the DSSC from $3.55 \% \rightarrow 5.46 \%$ for $L = 3 \mu\text{m} \rightarrow 12 \mu\text{m}$ respectively From the results, scaling of the WE can be considered as an critical component for light harvesting in DSSC system which further improves the η .

Variations in TiO_2 micro/nano structure shape, size and crystal phase have the potential to improve the DSSC's performance by improving dye loading and better light scattering, or faster electron transportation and longer electron lifetime. DSSC can be viewed as important factors, which have considerable potential to optimize its performance by controlling electrode (WE) thickening, slurry or paste preparation and composition, particle form, size, porosity and its distribution in the oxide layer. The EIS curved fitting technique for the evaluation of electron kinetics and their lifetime over TiO_2 /interface electrolyte's is a cost-effective tool to examine the charge transport properties. The discussed modifications can be considered in order to modulate the physical and chemical properties of WE to enhance PV performance of DSSC.

6.2 Future Scope

Inspite of achieving great development in photovoltaic performance (PV) (η), DSSCs are still under research to match the efficiency with those of conventional Si-based solar cells. However DSSC has attracted significant attention of both scientists and market globe wide for last few decades. The cost effective fabrication process of DSSCs make them viable and efficient solar cells. It is observed that low cost to commercialize DSSCs along with better improved PV performance may replace conventional solar cells near future. Various research groups are continuously performing experiments for improving the efficiency and viability of the cell. A widespread study has already started to achieve significant gain in the efficiency. These include

the use of efficient photo sensitizers to inject the photo generated charge carries into the working electrode, solid state electrolytes for better temperature response, synthesis routes to transform morphology and crystalline property of electrode etc. The DSSC can produce electricity under low light conditions, including indoor lighting. Due to the structural design and different color dyes, the cell features colors and transparency. Therefore, DSSCs can be used on architecture, interior applications, electronic devices, and portable power systems.

Curriculum Vitae

DEEPAK KUMAR

Asst. Professor (Senior Scale)

Vidwan Id: <https://vidwan.inflibnet.ac.in/profile/89273>

Department of Electrical and Electronics Eng.

University of the Petroleum and Energy Studies

Area of Research

VLSI Microelectronics, Semiconductor Devices (TFETs, OSC, DSSC, OTFT)

Solar cell Technology, Device to Circuit Transformation using Verilog-A.

Education

Year of Passing	Degree/Certificate	Institute	%/CGPA
2015	M. Tech in Microelectronics, VLSI & Display Technology	Indian Institute of Technology, Kanpur	7.0/10
2011	B. Tech in Electronics Engineering	Harcourt Butler Technological Institute, Kanpur	66.05 %
2006	Intermediate (CBSE)	Wood Row School	66.0 %
2004	Matriculation (CBSE)	Wood Row School	61.8 %

Academic Responsibilities

1. Faculty Counsellor of IEEE Student Branch(STB 10991), Electrical and Electronics Eng. Department, UPES.
2. Faculty Coordinator of Spoken Tutorial Program, IIT-B (MHRD India) at Electrical and Electronics Eng. Department, UPES.

Research Projects

1. Effect of particle morphology on efficiency of Dye Sensitized Solar Cells (DSSC).
2. Fabrication of electronic device for quantitation of chemical compounds based on colorimetric analysis.
